Background: Autologous adipose tissue injection is used in plastic surgery for correction of localized tissue atrophy and has also been successfully offered for treatment of localized scleroderma. We aimed to evaluate whether patients with systemic sclerosis (SSc) and facial handicap could also benefit from this therapy.

Methods: We included 14 patients (mean age of 53.8 ± 9.6 years) suffering from SSc with facial handicap defined by Mouth Handicap in Systemic Sclerosis Scale (MHISS) score more than or equal to 20, a Rodnan skin score on the face more than or equal to 1, and maximal mouth opening of less than 55 mm. Autologous adipose tissue injection was performed under local anesthesia using the technique of subcutaneous microinjection. The main objective of this study was an improvement of the MHISS score 6 months after the surgical treatment.

Results: The procedure was well tolerated. We observed a mean decrease in the MHISS score of 10.7 points (± 5.1 ; $P < 0.0001$) at 6 months (35% improvement). Secondary efficacy parameters assessing perioral skin sclerosis, maximum mouth opening, sicca syndrome, and facial pain significantly improved at 3 and 6 months postsurgery. At a 6-month follow-up, 75% of patients were satisfied or very satisfied of the adipose tissue microinjection therapy.

Conclusions: Our study suggests that subcutaneous perioral microfat injection in patients with SSc is beneficial in the treatment of facial handicap, skin sclerosis, mouth opening limitation, sicca syndrome, and facial pain. Thus, this minimally invasive approach offers a new hope for face therapy for patients with SSc. Facial manifestations have been described in systemic sclerosis (SSc) since the end of the 1980s.¹ Patients with SSc often have perioral skin sclerosis leading to mouth opening limitation (MOL), interfering considerably with eating, speaking, oral hygiene, intubation, and dental treatment.¹ In the study by Vincent et al² on 30 patients with SSc, face cutaneous hardening was found in more than 90% of cases, with facial cutaneous atrophy (93%), perioral wrinkles with disappearance of the frontal folds (83%), and MOL (70%). Xerostomia is also a frequent symptom that concerns 70% of the patients.^{1,3} Temporomandibular pain can be observed in 30% of cases.² It is estimated that orofacial manifestations concern almost 80% of patients with SSc.^{2,4} To date, face involvement can be considered by physicians as a minor consequence of

the disease and can often be overlooked. Nevertheless, this facial transformation can be disfiguring and be a source of functional, aesthetic, and social discomfort with a significant psychological stress for patients.

In recent decades, autologous adipose tissue (AT) grafting has been successfully used to correct volume and contour defects. In addition to a filling effect, grafted fat seems to influence dynamic tissue regeneration at the recipient site^{5,6} and is commonly used for the regeneration of the skin for different indications such as radiodermitis,⁷ wound healing,⁸ and localized forms of scleroderma such as “en coup de sabre scleroderma.”⁹⁻¹¹

When compared with Coleman fat grafting, microfat grafting¹² that involves the harvest and injection of only microlobules of AT (around 500 µm) was able to decrease skin fibrosis and improve peripheral vascularization in mice with bleomycin-induced skin sclerosis.¹³ It was recently demonstrated that in vitro viability and migration of isolated adipose stromal cells (ASCs) obtained from micro-harvested lipoaspirates were significantly higher than the conventional fat harvesting by the Coleman cannula (3 mm, 1-hole blunt tip). Moreover, a significant high adherence rate of isolated ASCs from the microfat harvesting technique onto matrices was observed.¹⁴ Thus, we suggested that microfat grafting may be more suitable for tissue-regenerative approach in SSc. In this study, we aimed to assess for the first time the safety and efficacy of autologous microfat grafting in the face of patients with SSc and facial handicap.

PATIENTS AND METHODS

Study Design, Subjects, and Eligibility Criteria

This was a single-center, open-label study performed in Marseille (France). Longitudinal intra-

subject analyses were performed. Inclusion criteria were as follows: (1) Mouth Handicap in Systemic Sclerosis Scale (MHSS) score more than or equal to 20 [(0–48)¹⁵; Table 1], (2) Rodnan skin score on the face more than or equal to 1 (ie, mild skin sclerosis on a scale from 0 to 3), and (3) maximal mouth opening of less than 55 mm. The main characteristics of 14 patients are shown (Table 2). No patient was treated with a dose of steroids more than 10 mg/day or with cyclophosphamide on entering the study. Two patients were treated with mycophenolate mofetil and 2 others with methotrexate. One patient died 44 days after the surgical treatment from an acute disease unrelated to the autologous fat grafting. One patient refused the 6-month follow-up. Thus, only 12 patients were assessed at 6 months. Patients were asked not to change their regular medications and physical therapy of the face during the trial.

This study was registered with ClinicalTrials.gov number NCT02206672. The Local Patient Protection Committee expressed a favorable opinion, and informed consent for patients’ participation in this study was obtained.

Tissue Collection and Fat Preparation

Surgery was performed by the same surgeon under local anesthesia using the technique of subcutaneous microinjection of autologous fat.¹² The zones of liposuction were marked before surgery, with a priority for the inner side of the knees, followed by the abdomen and hips. The entry points for the infiltration cannula were anesthetized with pure 1% adrenaline and lidocaine with a 30-gauge (0.25 mm) needle. An infiltration was then carried out in the area with a 14-gauge cannula with 10 ml of 1% adrenaline and lidocaine diluted in 20 ml of physiological salt solution, with an injected volume

Table 1. The Mouth Handicap in Systemic Sclerosis scale¹⁵

		Never	Rarely	Occasionally	Often	Always
1.	I have difficulties opening my mouth	0	1	2	3	4
2.	I have to avoid certain drinks (sparkling, alcohol, acidic)	0	1	2	3	4
3.	I have difficulties chewing	0	1	2	3	4
4.	My dentist has difficulties taking care of my teeth	0	1	2	3	4
5.	My dentition has become altered	0	1	2	3	4
6.	My lips are retracted and/or my cheeks are sunken	0	1	2	3	4
7.	My mouth is dry	0	1	2	3	4
8.	I must drink often	0	1	2	3	4
9.	My meals consist of what I can eat and not what I would like to eat	0	1	2	3	4
10.	I have difficulties speaking clearly	0	1	2	3	4
11.	The appearance of my face is modified	0	1	2	3	4
12.	I have trouble with the way my face looks	0	1	2	3	4

The MHSS contains 12 items with 5 levels of answers (total score range: 0–48). The first factor (5 items: items 1, 3, 4, 5, and 6) represents handicap induced by reduced mouth opening, the second (5 items: items 7, 8, 9, and 10) handicap induced by sicca syndrome, and the third (2 items: 11 and 12) aesthetic concerns.

†Global modified Rodnan skin score was calculated according to Clement et al.¹⁸

at each entry point of 0.5 ml. Liposuction was performed with a 14-gauge (2-mm cannula height holes of less than 1-mm blunt tip) connected to a faucet in 3 ways with 2 valves antireturn, with a 10-ml syringe maintaining the plunger in contact with the fat tissue and with a negative pressure less than 350 mm Hg. The number of sites of fat harvest was between 2 and 4 per patient.

The harvested fat was directly injected into a closed-circuit PureGraft 50 ml system filtration pocket (Puregraft, San Diego, Calif.). The PureGraft system allows the purification of AT by elimination of fluid excess, lipid phase, blood cells, and fragments through filtration by membrane in a sterile environment. The quantity of harvested fat was about 50 ml per patient, which allowed obtaining a final volume

of pure fat ranging from 20 to 25 ml. The cleaned tissue was directly retrieved by connecting the Pure-Graft system to syringes of 1 ml to allow a precise re-injection into the face.

Fat Delivery

Entry points were anesthetized with 0.5 ml of pure 1% adrenaline and lidocaine using a 30-gauge (0.25 mm) needle. Four entry points were determined in the perioral region: 2 at the level of nasogenien grooves (1 cm from the corner of the mouth) and 2 at the level of the lower lip (1 cm below each corner of the mouth).

The penetration of the skin and the dermis was carried out using a 21-gauge (0.8 mm) needle, which was then replaced by a cannula of the same diameter. Subcutaneous injections were performed into different directions from each injection site. The quantity of fat to be injected was determined based on the morphology of patient's face.

Assessment of Safety and Efficacy

Safety was assessed at day +7, day +21, and 3 and 6 months after the procedure. Facial handicap was assessed by the MHISS,¹⁵ which includes 12 items (score 0–48) and estimates 3 domains: handicap induced by MOL and sicca syndrome, and aesthetic facial concerns. The following secondary efficacy parameters were assessed at 3 and 6 months. (1) Skin sclerosis: Rodnan skin score on face (0 = normal skin; 1 = mild thickness; 2 = moderate thickness; and 3 = severe thickness with inability to pinch the skin into a fold), maximal mouth opening between the incisive edge of the upper and lower first incisors measuring in millimeters,¹⁹ visual analog scale (VAS; 0–100) for mouth opening, and skin elasticity assessed by a suction skin elasticity meter (Cutometer dual MPA 580, Courage & Khazaka Electronic GmbH, Cologne, Germany) at 4 locations (2 points in the nasolabial region and 2 points in the cheekbone region) using Dobrev's parameters with a 2-mm diameter measuring probe.²⁰ (2) Sicca syndrome: Xerostomia Inventory questionnaire (11 = no discomfort to 55 = severe discomfort; Table 3),^{21,22} sugar test (time required to melt a sugar without crunching it), and VAS (0–100) for sicca syndrome. (3) Pain induced by the palpation of masseters and temporal muscles (VAS 0–100) and facial pain (VAS 0–100). (4) Volumizing and aesthetic effect: standard photographs performed by the same operator and with the same incidences and light. (5) Satisfaction assessment: Patients were asked to fill out a 4-point scale from very satisfied to unsatisfied, 6 months after fat microinjection. (6) Global disability: The Health Assessment Questionnaire (HAQ) adapted to SSc

Table 3. The Xerostomia Inventory²¹

Xerostomia Inventory Questions	
1.	I sip liquids to help swallow food
2.	My mouth feels dry when eating a meal
3.	I get up at night to drink
4.	My mouth feels dry
5.	I have difficulty in eating dry foods
6.	I suck sweets or cough lollies to relieve dry mouth
7.	I have difficulties swallowing certain foods
8.	The skin of my face feels dry
9.	My eyes feel dry
10.	My lips feel dry
11.	The inside of my nose feels dry

The Xerostomia Inventory is an 11-item summated rating scale that results in a single continuous scale score representing the severity of chronic xerostomia with 5 levels of answers (total score range: 11–55).

Response options: Never (scoring 1), hardly (2), occasionally (3), fairly often (4), and very often (5).

The minimally important difference to reflect deterioration in xerostomia symptoms was in a previous series of 6 scale points.²²

(SSc-HAQ) was used. It includes the HAQ disease index and 5 specific VAS (scale 0–3).²³

Statistical Analysis

Adverse events were coded by the dictionary MedDRA (Medical Dictionary for Regulatory Activities). Efficacy endpoints were continuous or ordinal variables. Data are shown as mean ± SD and median and range (1st quartile to 3rd quartile). Results of the assessment at 3 and 6 months of the procedure were compared from baseline using a single sample test on mean of 0. Normal distribution was examined by Shapiro-Wilk test. Normally distributed were analyzed by 1 sample *t* test. Nonparametric data were analyzed by Wilcoxon signed-rank test. Spearman *r* coefficient for correlation test was used. A nominal $P \leq 0.05$ (2 sided) was considered significant. Results were not corrected for multiple comparisons. Statistical analyses were performed using SAS (SAS Institute Inc., version 9.2, Cary, N.C.).

RESULTS

Fourteen patients with SSc, all women, with mean age of 53.8 years (±9.6) were enrolled and treated in the same month (Table 2).

Safety Assessment

Mean quantity of purified fat injection was 16.3 ml (±4.7 ml) and median quantity was 17 ml with extremes from 6.2 to 23 ml. The surgeon noticed difficulties in fat reinjection for 5 patients because of skin fibrosis but without preventing the good progress of surgery. The duration of the procedure from skin disinfection to bandages was 60 to 90 minutes.

No infectious complication related to the procedure was recorded. As classically reported after lipo-

suction, small areas of bruising at the zones of fat harvest were observed in 8 patients and local pain in 3 patients. Concerning perioral fat reinjection, injection site bruising (n = 3), pain (n = 3), perioral sensitive manifestation (n = 1), and trigeminal neuralgia (n = 1) were observed. All symptoms were of mild to moderate intensity and spontaneously resolved in a few days.

Improvement of MHISS Score in Systemic Sclerosis Patients Treated by Autologous Fat Microinjection

At baseline, the mean MHISS score was 32.6 (±6.3) and significantly decreased to 25.3 (±11.7) at 3 months and to 21.8 (±8.9) at 6 months. The reduction of the MHISS score at 6 months corresponded to a 34.6% of improvement from baseline, with a mean decrease in the MHISS score of 10.7 points (±5.1; $P < 0.001$). A 50% improvement of the MHISS score was observed for 3 patients 3 months after the procedure, and lasted until the 6-month follow-up (Table 4). Contribution of each domain of the MHISS score showed improvement. For “oral opening” domain (on 24 points), we noticed a significant improvement of 3.2 points (±6.3) at 3 months and 5.9 points (±3.9) at 6 months. For “dry syndrome” domain (on 16 points), a significant improvement of 2.4 points (±2.7) at 3 months, which was lasting at 6 months (2.4 points ±1.7), was also observed. Finally, for “aesthetic concerns” domain (on 8 points), a significant improvement of 1.5 (±1.8) at 3 months and 2.3 (±1.9) at 6 months was noted.

The MHISS score was not different according to the cutaneous limited or diffuse subgroup, respectively, at baseline of 33.7 (±3.9) and 31.8 (±7.8; $P = 0.593$). Both subgroups improved at 3 months to 25.2 (±13.0) and 25.4 (±11.8; $P = 0.980$) and at 6 months, respectively, to 21.0 (±7.0) and 22.3 (±10.2; $P = 0.832$). No correlation between the MHISS score improvement and the volume of injected fat was observed at both tested periods (month 3: $r = -0.12$, $P = 0.707$ and month 6: $r = -0.11$, $P = 0.729$).

Evaluation of Facial Skin Fibrosis

Although the global modified Rodnan skin score did not change during the study, a 57.7% and 54.2% reduction of the face-specific modified Rodnan skin score was observed at 3 ($P = 0.008$) and 6 months ($P = 0.016$), respectively (Table 5). When focused on the perioral area, a 79.5% and 65.3% improvement of the skin sclerosis was observed at 3 ($P < 0.001$) and 6 months ($P = 0.002$), respectively.

Mouth opening significantly increased at 3 (+3.7 ± 3.8 mm) and 6 months (+3.7 mm ± 4.4 mm). There was a significant decrease in the VAS assessing discomfort related to MOL at 3 (35.7%) and

Table 4. MHISS Outcome After Microinjection of Autologous Adipose Tissue in the Face of Patients with SSc (Total Score and Details on the 3 Domains of the Score)

	Inclusion (Baseline)	3 mo (n = 13)	Change (3 mo–Baseline)	P Value*	6 mo (n = 12)	Change (6 mo–Baseline)	P Value†

*P value from baseline to 3 mo.

†P value from baseline to 6 mo.

6 months (52.2%; $P < 0.001$). Cutometer measurement of skin elasticity showed that there was no significant change at 3 and 6 months of the procedure (data not shown).

Evaluation of the Oral Sicca Syndrome

At 3 and 6 months after fat grafting, the Xerostomia Inventory score significantly improved with a reduction of 5.2 points (±4.9) at 6 months. A significant decrease in the time to melt a sugar on the tongue of 1 minute 22 seconds (±1 minute 29 seconds) in comparison with baseline was observed at 6 months. In this context, a 57.7% and 53% reduction of the VAS focused on handicap related to dry mouth was observed at 3 ($P < 0.001$) and 6 months ($P = 0.003$), respectively.

Evaluation of Facial Pain

Pain induced by the palpation of the muscles of the face was mild at inclusion, but it significantly improved at 3 and 6 months ($P = 0.025$ and $P = 0.006$, respectively). Similarly, VAS for facial pain showed a 39.4% reduction at 3 months ($P = 0.027$) and a 62.8% reduction at 6 months ($P = 0.010$).

Volumizing and Aesthetic Effects Assessed on Standard Photographs

Improvement of perioral folds and mouth opening was clinically obvious for some patients as illustrated in Figures 1 through 6.

Patient's Satisfaction

At 6 months of the procedure, 9 of 12 patients declared to be either very satisfied (n = 4) or satisfied (n = 5), 2 patients moderately satisfied, and 1 patient remained unsatisfied.

Impact on Global Disability

When assessing the impact of the therapy on global disability related to the disease, no significant change was observed: mean SSc-HAQ score at inclusion was of 1.26 points (±0.38) and remained at 3 and 6 months, respectively, of 1.07 (±0.53) and 1.25 (±0.74). No significant correlation between the MHISS score and the SSc-HAQ score was observed whatever the tested period (month 0: $r = 0.23$, $P = 0.133$; month 3: $r = 0.54$, $P = 0.053$; and month 6: $r = 0.30$, $P = 0.336$).

DISCUSSION

Facial handicap in scleroderma patients is often overlooked, but it is highly important for the patient's quality of life, and therapeutic approaches are lacking. Until now, standard treatment has relied on a facial stretching program approach, but the observed functional improvement seems to be largely dependent on the continuity and repetition of exercises.²⁴

The goal of our study was to assess whether autologous fat microinjection can improve facial sclerosis, sicca syndrome, aesthetic aspects, and quality of life. Our study shows that autologous AT microinjection is safe in patients with SSc and improves facial handicap, as shown by the significant reduction of the MHISS score at 3 and 6 months after surgery including a significant improvement for each domain (mouth opening, sicca syndrome, and aesthetic discomfort). Complementary parameters specifically assessing mouth opening (such as maximal mouth opening measure) and sicca syndrome (such as Xerostomia Inventory and sugar test time) confirmed the significant improvement at 6 months. Thus, both subjective and objective parameters confirmed the beneficial results.

†P value from baseline to 6 mo.

Fig. 1. A 58-year-old patient with a diffuse cutaneous form of systemic sclerosis before (M0) surgery.

Fig. 3. A 67-year-old patient with a limited cutaneous form before (M0) surgery.

Fig. 2. The same patient at 6 months (M6) of the reinjection of 16 ml of adipose tissue on the face.

Fig. 4. The same patient after 6 months (M6) of the microinjection of 11.6 ml of adipose tissue.

Del Papa et al²⁵ recently reported a significant clinical improvement in oral opening in 20 patients with SSc using the Coleman method. This study showed safety and feasibility of a different surgical procedure and a significant improvement of the mouth opening capacity after perioral fat grafting, with a benefit obtained as early as 3 months after the procedure. In comparison with our study, a similar mean quantity of purified fat reinjection was performed (16 ml), and the statistically significant increase of the maximum interincisive distance at 3 months in the study by Del Papa et al (mean, +2.63 mm) was very close to the one observed in this study (+3.7 mm).

To note, only patients with SSc with the diffuse cutaneous form were included in the study by Del Papa et al, whereas limited and diffuse cutaneous forms with facial skin sclerosis were included in this study. Follow-up was only 3 months in Del Papa et al's study design, whereas we performed a longer

follow-up of 6 months. Coleman's technique was used in the study by Del Papa et al, whereas we performed the microinjection protocol. Then, we used the PureGraft filtration technique that offers a better fat quality by reducing blood cell and free lipid content, with a greater AT viability when compared with gravity separation and centrifugation methods.¹⁴ We used the MHISS questionnaire validated in patients¹⁵ with SSc that allowed us to appreciate the positive effect on facial handicap in 3 domains: reduction in mouth opening, sicca syndrome, and aesthetic concerns. We also specifically analyzed the sicca syndrome and showed an improvement of the Xerostomia Inventory questionnaire and the delay to melt a sugar on the tongue and the VAS focused on handicap related to sicca syndrome. Thus, this study demonstrates that not only autologous fat graft has a beneficial effect on skin sclerosis in both limited and diffuse cutaneous forms of the disease but also that

Fig. 5. A 60-year-old patient with a diffuse cutaneous form of the disease when opening the mouth before surgery (M0).

Fig. 6. The same patient after 6 months (M6). Mouth opening was of 25 mm at inclusion and 35 mm at M6.

the effect persists up to 6 months and has benefits extending to facial handicap, sicca syndrome, and facial pain.

The beneficial effect of autologous AT microinjection cannot be ascribed solely to the filling effect because no correlation between the MHISS scores' improvement and the volume of fat reinjection was shown in our study.

The trophic properties of AT are mainly because of the stromal vascular fraction (SVF) of AT, which appears to have angiogenic, antiinflammatory, and immunomodulatory effects.²⁶ SVF contains mesenchymal stem cells (called ASCs), endothelial progenitor cells, hematopoietic cells, preadipocytes, and pericytes.^{26,27} ASCs are able to differentiate into the cells of various lineages,^{26,27} to secrete angiogenic factors, and to have an immunomodulatory effect that appear to involve different mechanisms.^{28,29} Hematopoietic and endothelial progenitor cells^{27,30} are able to promote the vascular growth or vascular repair by the secre-

tion of major growth factors and cytokines involved in wound healing and neovascularization and could limit tissue damage by the production of antiapoptotic and antiinflammatory factors.^{26,27,31,32} Innate immunity cells and cells of adaptive immunity are likely to participate in an important immunoregulatory effect but are still poorly documented. The role of these subpopulations in the beneficial effect observed in fat graft is still unknown. It is hypothesized that AT-derived cells fraction of the unprocessed AT including adipocytes and SVF may create an optimal environment that protect the perivascular niche and support the regenerative effect of cells and growth factors within host tissues. ASC-based therapy have recently shown interest in localized scleroderma: Scuderi et al³³ assessed the effect of local injections of a combination of ex vivo expanded ASC and hyaluronic acid solution in 6 patients with morphea. They reported an arrest of local disease progression, a regression of dyschromia, and an improvement of skin softening and sensitivity.

One limit of current and previous studies is the time frame of the follow-up. Although convention would suggest that the maximal effects of fat grafting can be assessed as early as 3 months after injection, there is a need for long-term follow-up on the background of the SSc phenotype. For that, we planned to evaluate patients 12 months postsurgery. Faced with these encouraging results obtained in open-labeled studies, larger and controlled studies in scleroderma disease are required.
