Abstract Quaternary tectonic and denudation rates are investigated for an actively growing basement anticline: the Sierra Pie de Palo range, which belongs to the Andean foreland of Northwestern Argentina (28°S–33°S). In this study, a detailed morphometric analysis of the topography is combined with in situ-produced cosmogenic ^{10}Be concentrations measured in (1) surface boulders abandoned on alluvial terraces affected by fault activity (along the north bounding fault) and growth of the basement fold (along the southeastern border), (2) bedrock outcrops corresponding to an exhumed and folded, regional erosion surface, and (3) fluvial sediments sampled at the outlets of several watersheds. Along the eastern and northern borders of the range, incision and uplift rates have been estimated at approximately 0.5 and 1 mm/yr when integrated on Holocene and Pleistocene time scales, in close agreement with both long-term (structural and basin evolution data) and short-term (GPS-derived velocity field) analyses. Cosmogenic-derived denudation and uplift rates combined with geomorphic characteristics of watersheds and river channels allows estimating the onset of the uplift at 4–6 Ma, followed by a more recent period of topographic rejuvenation at roughly 1–2 Ma, probably synchronous with steepening of the eastern and northern flanks of the anticline.

1. Introduction

Quantification of relief creation is an important step in studying mountain building processes. Because relief development is mainly the result of complex interactions between tectonics and climate [Molnar, 2009], examining relief changes with time not only requires quantification of tectonic deformation but also insights into the location and magnitude of erosional processes [Champagnac et al., 2014; Godard et al., 2014]. In active tectonic settings, faults grow by repeated coseismic displacements, increasing their cumulative offsets with time. In compressional domains, most reverse or thrust faults are commonly associated with folds; their lateral propagation and vertical movement produce deformation of the Earth's surface in the form of flexures, which can be directly used to identify major areas of crustal or lithospheric deformation. Where reverse or thrust faults are hidden or even blind, the topographic disturbances caused by fold growth may be identified in the landscape, such as in the drainage network incising the uplifting structures [Molnar et al., 1994; Jackson et al., 1996]. However, there are only few cases for which the growth rates have been successfully determined using a well-constrained chronological framework [e.g., Jackson et al., 2002].

Located in the Andean foreland of Northwestern Argentina, the Sierra Pie de Palo (SPDP) range is a case study to quantify relief creation. The SPDP is an active basement anticline, the growth of which is controlled by crustal-scale reverse faults [Régnier et al., 1992; Smalley et al., 1993; Zapata, 1998; Ramos et al., 2002] and evidenced by the folding of a regional erosional surface exhumed from the Andean foreland Bermejo basin [Jordan et al., 1989]. In this region, a desert climate combined with high rates of tectonic deformation provides high-preservation potential of deformed geomorphic features. Indeed, the growth of the SPDP interfered with the impact of fluvial activity, resulting in stepped fluvial terraces that are uplifted, tilted, and/or faulted. Dating such geomorphic features using cosmic ray exposure (CRE) techniques has become a common method to estimate rates of tectonic deformation [e.g., Gosse and Phillips, 2001]. Even if this approach has been applied

to several sectors in this Andean region [Siame *et al.*, 1997, 2002; Meigs *et al.*, 2006; Schmidt *et al.*, 2011, 2012; Hedrick *et al.*, 2013], this area still lacks of a well-constrained chronological framework for alluvial deposition and abandonment.

In this study, we present new in situ-produced cosmogenic ^{10}Be data from this actively deforming and arid region of Northwestern Argentina. Thanks to a combination of detailed geomorphic and topographic analyses with CRE dating and quantification of denudation rates, we investigated the Plio-Quaternary uplift history of the SPDP. In situ-produced ^{10}Be concentrations were measured in (1) surface boulders abandoned on stepped alluvial surfaces affected by fault activity along the eastern and northern borders of the SPDP, (2) bedrock outcrops corresponding to the exhumed regional erosional surface, and (3) fluvial sediments sampled at the outlets of several watersheds that incised this erosional surface. The obtained results constrain the incision rates and provide minimum estimates on the Holocene and Pleistocene uplift rates associated with the growth of the SPDP. We also determined catchment-wide denudation rates that are 1 order of magnitude higher than bedrock denudation rates. Cosmogenic-derived denudation and uplift rates combined with geomorphic characteristics of watersheds and river channels allows estimating the onset of the uplift at 4–6 Ma, followed by a more recent period of topographic rejuvenation at roughly 1–2 Ma, probably synchronous with steepening of the eastern and northern flanks of the anticline.

2. Regional Setting of the Andean Foreland of Northwestern Argentina

The Andean foreland of Northwestern Argentina (28°S–33°S) is located above the flat subduction of the Nazca Plate beneath the South American lithosphere [Cahill and Isacks, 1992; Yáñez *et al.*, 2001; Anderson *et al.*, 2007] ongoing at a rate of about 8 cm/yr with an azimuth of N74°E (Figure 1a) [DeMets *et al.*, 1990]. In this region, two compressional, opposite verging structural provinces are facing: the east verging, thin-skinned Argentine Precordillera (AP) fold-and-thrust belt and the west verging, thick-skinned Sierras Pampeanas (SP) basement uplifts (Figures 1b and 1c) [Ortiz and Zambrano, 1981; Ramos *et al.*, 2002; Vergés *et al.*, 2007].

The progressive shallowing of the Nazca slab induced a change in the geochemical properties of the Neogene volcanic rocks and subsequently the cessation of volcanic activity at roughly 7–6 Ma in the AP [Kay and Abbruzzi, 1996] and between 4.7 and 2 Ma in the SP [Gordillo and Linares, 1981; Kay *et al.*, 1991; Kay and Gordillo, 1994; Urbina *et al.*, 1997]. It also induced enhanced plate coupling [Jordan *et al.*, 1983; Jordan and Allmendinger, 1986; Smalley *et al.*, 1993] as well as thermal weakness of the crust associated with eastward migration of the magmatic arc [Ramos *et al.*, 2002], which have long been considered to be responsible for thick-skinned basement uplifts in the SP.

In the AP, the timing of the craton-ward fold-and-thrust belt development has been determined through detailed magnetostratigraphic and growth strata studies of the synorogenic materials deposited within intramountain basins and the Bermejo Valley [Jordan *et al.*, 1993; Zapata and Allmendinger, 1996]. In the Western AP, this deformation started at 19–20 Ma and propagated to the Central AP from 10–12 Ma to roughly 5 Ma [Jordan *et al.*, 1993; Zapata and Allmendinger, 1996; Perucca and Onorato, 2011]. During the last 5 Ma, regional deformation concentrated along the west verging Eastern AP thrusts and folds, synchronous with the basement uplifts in the western SP [Jordan *et al.*, 1993; Zapata and Allmendinger, 1996; Ramos *et al.*, 2002].

In the northern SP (28°S), stratigraphic data [Strecker, 1987] and apatite fission track [Coughlin *et al.*, 1998] studies allows bracketing the main uplift of the Sierra Aconquija between 7.6–6.0 and 4.0–3.4 Ma [Ramos *et al.*, 2002]. Farther south (29°S), magnetostratigraphic [Tripaldi *et al.*, 2011] and isotopic [Tosselli, 1996; Losada-Calderón *et al.*, 1994] studies suggest an uplift inception between 4.5 and 4.2 Ma in the Sierra Famatina [Ramos *et al.*, 2002]. To the south (Sierra de Córdoba and Sierra de Chepes), ages of volcanic series (Figure 1b) [Kay and Abbruzzi, 1996; Kay and Gordillo, 1994; Gordillo and Linares, 1981] suggests an uplift timing between 6.0 and 5.5 Ma [Ramos *et al.*, 2002].

For the SPDP, the thermal modeling of apatite fission tracks and (U-Th)/He ages supports an onset of final cooling and exhumation of this western Pampean range between Cretaceous and Paleogene time (at about 60 Ma), in relation with an early phase of Andean compression [Löbens *et al.*, 2013b]. These authors also proposed that the relief associated with the SPDP may have existed since the Mesozoic [e.g., Carignano *et al.*, 1999]. Conversely, Ramos *et al.* [2002] suggested that the exhumation of the SPDP started at roughly 3 Ma (Figure 1b), controlled at depth by a midcrustal wedge, with average shortening and uplift rates of about 4 and 1 mm/yr, respectively. Finally, the exhumation of this range has alternatively been described as a result

Figure 2. Geomorphic characteristics of the Sierra Pie de Palo. (a) Morphometric map of watersheds and piedmont deposits of the SPDP. Watersheds contours have been extracted from the SRTM90 DEM and are colored according to their hypsometric integral values. Alluvial fans have been mapped using Landsat and SPOT images, as well as SRTM90 DEM and derived slope grid. They are colored according to their slope values, averaged over alluvial area around the sample pixel. Both $\approx$ N-S (A-A') and $\approx$ E-W (B-B') topographic cross sections have been extracted from the SRTM90 DEM (thick solid lines) and the reconstructed regional erosion surface (thick dotted lines). (b) Map of the topographic ridges extracted from the SRTM90 DEM. (c) Map of the surfaces with local slope lower than 10° extracted from the SRTM90 DEM. (d) DEM of the surface envelope of the SPDP (overlaid on the SRTM90 DEM) reconstructed by interpolation of the elevation points extracted from the ridges (Figure 2b) and low-slope areas (Figure 2d). (e) Map of the vertical incision derived from the subtraction of the envelope surface and the SRTM90 DEM. Spatial integration of these vertical incision values yield to the estimation of a minimum eroded volume of roughly 135 km^3 . Keys: GEM, Grande El Molle lineament; GL, Guayaupa-Lima lineament.

of cataclastic diapirism, which is proposed to produce dome-like topography at the surface due to lateral compressive forces and density differences [Vita-finzi, 2009].

Since roughly 150 years ago, this region experienced several large earthquakes, with the most recent events in 1944 (M_w 7.0), 1952 (M_w 6.8), and 1977 (M_w 7.4) (Figure 1c) [Kadinsky-Cade et al., 1985; Langer and Hartzell, 1996; Alvarado et al., 2005; Alvarado and Beck, 2006; INPRES, 2014; Perucca and Vargas, 2014]. The regional high level of crustal seismic activity is characterized by hypocentral depths ranging between 5 and 35 km [Smalley et al., 1993]. Most historical and large instrumental earthquakes are located to the east of the AP, with two main clusters of seismic activity centered below the Tullum-Ullum basins, close to the San Juan city, and around the SPDP, particularly along its eastern edge (Figure 1c). This seismicity pattern is also underlined by epicenter distributions from local seismic networks [Régner et al., 1992; Smalley et al., 1993], relocated teleseismic events [Engdahl and Villaseñor, 2002], and is in good agreement with the location of the regional active faults (Figures 1c and 1d). Close to the city of San Juan, it has been proposed that the fault responsible for the 1944 San Juan earthquake could be either the west verging thrusts associated with the Eastern AP [Siame et al., 2002; Alvarado and Beck, 2006] or an east verging, deep crustal thrust located beneath the Eastern AP thrust system [Meigs et al., 2006; Meigs and Nabelek, 2010; Rockwell et al., 2014]. Combining the relative locations of the double main shock and its aftershocks with observed coseismic elevation changes, Kadinsky-Cade et al. [1985] concluded that most of the coseismic slip associated with the 1977 Cauçete earthquake occurred on a west dipping fault, buried beneath the eastern flank of the SPDP. However, a common characteristic of these two large earthquakes is that only limited surface coseismic ruptures were produced.

3. Methods

In this study, the regional geomorphic characteristics of the SPDP have been investigated at the regional scale using an extract of the 3 arc sec (roughly 90 m) resolution digital elevation model (DEM) from the Shuttle Radar Topography Mission (SRTM) database (<ftp://e0srp01u.ecs.nasa.gov/srtm/version2/SRTM3/>), which has been postprocessed according to *Reuter et al.* [2007] to remove the no-data regions due to insufficient textural detail, characteristic of mountainous regions such as the Andes (<http://srtm.csi.cgiar.org>). The topographic grid has been processed in a Geographical Information System (Mapinfo), combined with Rivertools and Vertical Mapper softwares, to derive slope maps or vector objects like stream segments and watershed boundaries. Together with topographic and slope grids, a combination of SPOT panchromatic images and Landsat TM satellite images was used to map the alluvial landforms that skirt the piedmonts of the SPDP. Figure 2a presents a combination of these different geographic layers, with the main watersheds and the alluvial units mapped as a function of their hypsometric integral values and average slopes, respectively. At selected sites (see section 5), topographic surveys were performed with a total station (Leica TC 805), using the reference point 14-059 of the PASMA network (National Geographic Institute of Argentina), and planar coordinates (Gauss Krüger, Zone 2, and WGS84 datum).

To provide chronological constraints on alluvial terraces affected by fault activity and to estimate bounds on the denudation rates associated with the SPDP development, we used in situ-produced ^{10}Be concentrations resulting from spallation and muonic reactions on Silicon and Oxygen in quartz minerals. For complete reviews of in situ-produced cosmogenic techniques, one can refer to *Gosse and Phillips* [2001] and *Balco et al.* [2008] as well as to the supplemental material associated with this article. Measurements of in situ-produced ^{10}Be concentrations were performed at the French AMS national facility ASTER (CEREGE, Aix-en-Provence) [*Arnold et al.*, 2010]. The in situ-produced ^{10}Be results and derived minimum CRE ages and denudation rates are summarized in Table 1.

To examine the statistical significance of the cosmogenic nuclide-derived minimum CRE ages and maximum denudation rates, outliers were first identified applying the reduced chi-square statistic [*Ward and Wilson*, 1978] and the mean square weighted deviation (MSWD) for each group of samples. This allows accounting for the relative importance of both the internal and external reproducibility and comparing the observed variability defined by the uncertainties of the data [*McIntyre et al.*, 1966]. To downplay the weight of high or low outliers, another approach consists of applying a nonparametric bootstrap calculation of the central value for a given population of samples and its associated uncertainties. This bootstrap technique is particularly suitable for small data sets and/or when probability distributions are nonnormal [*Efron*, 1979; *Efron and Tibshirani*, 1986, 1993; *Davison and Hinkley*, 1997]. More importantly, it has the particularity of being statistically law independent. The numerical results of the MSWD and bootstrap analyses are presented in the supporting information associated with this article.

4. The Sierra Pie de Palo Range

4.1. Geomorphic Characteristics of the Sierra Pie de Palo Range

Located in the westernmost SP (Figure 1c), the SPDP is a NNE striking ellipsoid basement block (80 km long and 40 km wide) that reaches up to 3162 m elevation at Cerro Mogote (Figure 2a). As described above, it is an actively growing basement anticline [*Ramos et al.*, 2002] associated with a high level of crustal seismicity [*Régner et al.*, 1992; *Smalley et al.*, 1993], which forms a dissymmetrical arch with steeper slopes along its northern and eastern sides compared to its western and southern sides (Figures 2b and 2c) [*Siame et al.*, 2006]. The western long limb is dissected by two main gorges, superimposed on ENE-WSW basement lineaments (Guayaupa-Lima and Grande El Molle) (Figures 1c and 2a) [*Baldis et al.*, 1979; *Instituto Nacional de Prevención Sísmica (INPRES)*, 1982]. However, at least at a first order, neither NNW striking topographic sections nor the eastern front reveal any significant vertical or horizontal displacements associated with these basement structures, which probably remained inactive during Cenozoic times.

The relatively flat areas that comprise most of the SPDP topography define a convincing surface envelope along both N-S and E-W directions (Figures 2b and 2c). These flat surfaces are characteristic of most of the Pampean ranges and have long been referred to as the “Pampean peneplain” [*Jordan et al.*, 1989]. This erosion surface is probably polygenic, and its age is still a matter of debate, with stratigraphic data indicating that it may have formed after Middle Paleozoic to Cretaceous [e.g., *Jordan et al.*, 1989; *Carignano et al.*, 1999]. According to *Jordan et al.* [1989], this regional erosion surface has been deformed and exhumed during the

^aMeasured $^{10}\text{Be}/^9\text{Be}$ ratios and ^{10}Be concentrations used for determining minimum CRE ages and maximum denudation rates in the Sierra Pie de Palo area. Samples preparation followed a protocol adapted after Brown *et al.* [1991]. Measurements by accelerator mass spectrometry (AMS) were performed at the French AMS National Facility ASTER (CEREGE, Aix-en-Provence) [Arnold *et al.*, 2010]. $^{10}\text{Be}/^9\text{Be}$ ratios were calibrated directly against the National Institute of Standards and Technology standard reference material 4325 using an assigned $^{10}\text{Be}/^9\text{Be}$ value of $(2.79 \pm 0.03) \times 10^{-11}$ [Nishizumi *et al.*, 2007] and a ^{10}Be half-life of $(1.39 \pm 0.01) \times 10^6$ years as recommended by Korschin *et al.* [2010] and Chmeleff *et al.* [2010] according to their independent measurements. This standardization is equivalent to 07KNSTD within rounding error. In this study, 38 samples were prepared in two separated batches. A first series of 16 samples were prepared using a commercial carrier solution (Plasmanorm) leading to a process blank isotopic ratio of $(1.11 \pm 0.11) \times 10^{-14}$ (supporting information and section 3). A second series of 22 samples were prepared using an in-house carrier solution prepared from deep mined phenakite [Merchel *et al.*, 2008], leading to a process blank isotopic ratio of $(4.54 \pm 0.61) \times 10^{-15}$ (supporting information). Thickness of samples was comprised between 3 and 5 cm. Surface production rates were calculated following Stone [2000] and corrected for geomorphic shielding according to Dunne *et al.* [1999]. Muonic and spallogenic component parameters are those determined by Braucher *et al.* [2011]. Uncertainties on ^{10}Be concentrations are calculated using the standard error propagation method using the quadratic sum of the relative errors associated to the number of counts during 3600 s of measurement (N), AMS internal error (0.5% for ASTER), and error associated to procedural blanks [Arnold *et al.*, 2010]. Uncertainties on CRE ages and denudation rates propagate the ^{10}Be concentration uncertainties together with a conservative 15% error to account for variability of the production rates with time [Lal, 1991].

^bNA: Not available.

Neogene. Conversely, *Carignano et al.* [1999], *Rabassa et al.* [2010], *Löbens et al.* [2011, 2013a, 2013b], *Bense et al.* [2013], and *Enkelmann et al.* [2014] considered that Pampean reliefs may have persisted since the Mesozoic. Nowadays, the SPDP is only constituted by Paleozoic and Precambrian basement rocks, without any younger outcropping geological formations [*Ramos and Vujovich*, 2000]. East of the Bermejo Valley, at the same latitude as the SPDP, the southern tip of Sierra de la Huerta is partly covered by Triassic deposits that are affected by Quaternary deformation along the Las Chacras Fault [*Costa et al.*, 2000; *Siame et al.*, 2005] (Figure 1c). To the south, the SPDP is covered by the Late Quaternary sand dunes field of Medanos Grandes [*Tripaldi et al.*, 2010]. To the east and northeast of the SPDP, Pliocene deposits including materials derived from the AP suggest that the SPDP was once covered by Andean foreland deposits before being exhumed during the regional Neogene deformation [*Ramos and Vujovich*, 2000; *Ramos et al.*, 2002]. Whether the regional erosion surface formed during one or several denudation cycles is beyond the scope of this paper. However, it is an important regional geomorphic marker that allows gauging the deformation that has affected the SPDP.

The lithological characteristics and semiarid climate contributed to good preservation of the surface envelope of the basement fold. Consequently, considering that these conditions are fairly constant throughout the range, any tectonic perturbation should be discriminated using geomorphic indices associated with the drainage network. Among such indices, the hypsometric integral value, which is related to the degree to which a landscape is dissected, is commonly used to discriminate between tectonically active against inactive areas [*Strahler*, 1952]. This morphometric approach shows that the watersheds with higher integral hypsometric values are preferentially located along the northern and eastern flanks of the SPDP (Figure 2a). The elongated, almost rectilinear shape of the watersheds that dissect the northern and eastern flanks also correlate well with the steep slopes in these areas. Another line of geomorphic evidence for tectonic activity is the distribution pattern of the alluvial terraces that skirt the mountain periphery, with more alluvial generations along the northern and eastern flanks than at the toe of both the western and southern flanks. Furthermore, the average slope of these alluvial units increases up to 8–11° along the northeastern corner of the range, whereas it is elsewhere restricted to less than 4°, close to the original depositional slope (Figure 2a). All together, these geomorphic observations strongly suggest that most of the Quaternary deformation associated with this basement fold is concentrated along its northern and eastern flanks [*Siame et al.*, 2006].

To reconstruct the surface envelope of the SPDP, the ridges and local summits have been extracted from the SRTM DEM together with the areas where the local slope is lower than 10° (Figures 2d and 2e). This resulted in a database of elevation points that was then interpolated (Inverse Distance Weighting) to produce a theoretical surface envelope that can be considered as a relatively good proxy for the shape of the SPDP fold (Figure 2f). The difference between this theoretical envelope and the present-day topography represents the minimum volume of rocks that has been eroded by fluvial and hillslope processes since the SPDP has been uplifted. In Figure 2g, the present-day vertical incision is shown in map view and unveils total vertical incision as high as 700 m for the main valleys. The spatial integration of these vertical incision heights allows estimating a total eroded volume of about 135 km³.

4.2. Structural Model for the Sierra Pie de Palo Range

The SPDP is bounded by three regional tectonic structures (Figure 3). The major structure controlling the eastern border of the SPDP is a matter of debate. One possibility is the Ampacama-Nikizanga Fault, which runs for roughly 65 km with an average strike of N21°E, and has been described as an east dipping fault that splays at about 20 km depth off a midcrustal décollement in connection with the west verging, thick-skinned master fault bordering the Sierra de la Huerta, south of the Sierra Valle Fértil System [*Langer and Bollinger*, 1988; *Costa et al.*, 2000; *Ramos et al.*, 2002]. However, leveling surveys including after the 1977 Caucete earthquake [*Kadinsky-Cade et al.*, 1985; *Reilinger and Kadinsky-Cade*, 1985] as well as crustal reconstructions from shallow and deep seismic profiles [*Zapata*, 1998] favor a west dipping, east verging blind fault below the eastern border of the SPDP (Figure 3). This hypothesis is in good agreement with the observed first-order topographic signature of a steeper eastern flank and with the fact that, along most of the eastern flank length, the Neogene strata generally dip to the east and the Plio-Quaternary deposits are not affected by any major fault (Figure 4). To avoid any confusion with the previously described Ampacama-Niquizanga Fault, we refer to this crustal, antithetic thrust as the Eastern Pie de Palo Fault (EPF).

The northern boundary of the range is delimited by the North Pie de Palo Fault (NPF), a roughly E-W transpressive, left-lateral fault that extends over 80 km from the Matagusanos basin, south of the Mogna Anticline in the Eastern Precordillera [*Zapata*, 1998], to the Sierra de Valle Fértil Fault (Figure 3). This regional structure

Figure 3. Tentative structural model for the Sierra Pie de Palo. (a) Schematic structural map showing the major faults in vicinity of the SPDP. Same fault abbreviations than in Figure 1. (b) Schematic cross section (B-B') at about 31.5°S latitude showing the thick-skinned deformation front (modified after Vergés *et al.* [2007]); Central Precordillera after Von Gosen [1992]; Eastern Precordillera after Zapata [1998], Siame *et al.* [2002], and Alvarado and Beck [2006]; and structure at depth modified after Régner *et al.* [1992], Smalley *et al.* [1993], and Ramos *et al.* [2002].

coincides with a major northward change in the basement depth across the southern boundary of the Bermejo basin [Jordan and Allmendinger, 1986]. The NPF runs along the northern edge of the SPDP for approximately 26 km at the contact between the metamorphic basement and the Neogene foreland strata. This part of the NPF, referred as the Pajaritos Fault [Costa *et al.*, 2000], has a rectilinear trace, suggesting a relatively high dip to the south (at least 50–60°). At the northeastern corner of the SPDP, the Pajaritos Fault affects a series of alluvial landforms and exhibits a well-developed, 4 km long, north facing fault escarpment with a right-stepping relay that agrees well with a horizontal left-lateral component (Figure 5).

Finally, the southern half of the western SPDP side is bounded by the Tullum Fault System (TFS) [Zambrano and Suvires, 2008], which extends over 120 km farther south (Figures 1c and 3). This fault system is described as superimposed on the suture between the Cuyania and Precordillera terranes [Ramos *et al.*, 2002] and shows to the south of the SPDP limited and isolated bedrock (e.g., Cerro Salinas) exposures along strike (Figure 1c). Considering that the western border of the SPDP is relatively linear only along its southwestern termination and

Figure 4. Niquizanga area (southeastern SPDP). (a) Sample location map overlay on a combination of SPOT and Landsat images. (b) Field photograph toward the southwest showing the alluvial remnants stepped onto the SPDP lowermost topography. Alluvial units are labeled from T_0 corresponding to the present-day streambeds. (c) Panoramic photograph showing the dipping paleoerosion surface and its lateral relationships with the highest alluvial unit (HAU). (d) Topographic cross section constructed across the stepped alluvial remnants from field topographic survey. The HAU's elevation is projected onto the cross section for correlation. Numbers give the local river incision measured vertically below the alluvial remnants to the present-day streambed. Statistical analysis of CRE ages obtained for the alluvial units (T_2 , T_6 , and HAU). For each group of samples, outliers are identified (*); weighted mean (wm) and bootstrap mean (bs) are shown in the form of probability function plots (see also supporting information and section 3). Local incision rate derived from vertical incision measurements and CRE dating of the T_2 , T_6 , and HAU (solid blue squares). Assuming constant incision rate allows estimating the age bracketing (italic numbers) of the other alluvial units (solid orange squares).

Alluvial units are labeled from T_0 corresponding to the present-day streambed. Inset shows the location of Figure 5a. (b) Sample location map overlain on an extract of the Quickbird image. (c) Map view of the data acquired during the topographic survey (solid grey circles) locating the topographic profiles (thick red lines). The topographic profiles are depicted in Figure 6. (e) Field photograph of the 3 m high topographic escarpment affecting the younger T_1 alluvial unit. (Figures 5e and 5f) Bird's eye view photographs taken from a plane during a reconnaissance survey showing the different alluvial units and the topographic escarpment associated with the Pajaritos Fault.

the first-order topographic signature in both E-W and N-S directions, the TFS is likely to have been reactivated to accommodate the propagation of the SPDP toward the south.

To account for the geomorphic and topographic signatures presented in this paper and previously published geophysical interpretations [Volponi *et al.*, 1983; Kadinsky-Cade *et al.*, 1985; Reilinger and Kadinsky-Cade, 1985; Zapata, 1998], we consider that the development of the SPDP basement anticline should have been mainly controlled by (1) a blind, antithetic, east verging thrust fault located at depth below the eastern basement fold forelimb (EPF) and (2) a reverse, left-lateral crustal ramp (Pajaritos Fault) running along the northern border of the SPDP, which prevented its northward propagation.

5. Uplift and Denudation Rates

In the following sections, the morphotectonic settings of the sites selected for quantifying Quaternary rates of vertical incision and surface uplift are presented together with the obtained minimum CRE ages. The first

series of alluvial terraces is located along the southeastern border of the SPDP (Niquizanga) and allows deciphering rates of river incision and basement uplift associated with the growth of the fold above the buried EPF. The second series of alluvial terraces is located at the northeastern corner of the SPDP (Agua Brava) and allows estimating uplift rates associated with the eastern segment of the NPF (Pajaritos Fault). Finally, the selected sites for quantifying denudation rates associated with the growth of the SPDP basement anticline are presented together with the cosmogenic nuclide-derived denudation rates, allowing discussion of the influence of denudation processes on inferred tectonic rates.

5.1. Rates of Vertical Incision and Surface Uplift (SE Flank of SPDP, Niquizanga)

At Niquizanga (Figure 4), the Neogene strata plunge roughly 15–20° toward the east at the toe of the mountain range, in conformity with the plunge of the erosion surface cutting the basement rocks. Upward and eastward, the Neogene strata plunge diminishes, leaving only a slight angular unconformity with the overlying Quaternary alluvial deposits that skirt the mountain piedmont. This alluvial material derived from the SPDP form thin (<3–5 m) sedimentary deposits that overly the Neogene foreland strata exposed within incised cuts of the streambeds and can be arranged into two distinctive groups. The first group consists of alluvial terraces, labeled T_1 and T_2 with respect to the present-day streambeds (T_0), and a high alluvial unit, labeled HAU in Figure 4. Alluvial terraces T_1 and T_2 merge downstream with the bajada to the east of the mountain front. While alluvial terraces T_1 and T_2 generally stand less than several meters above T_0 , the HAU rises more than 50 m above the present-day streambeds (Figure 4). The alluvial terrace T_2 extends widely and exhibits relatively well-preserved, large boulders and subdued surface features like bars and swales. The second group consists of stepped, thin (<1 m) veneers of proximal alluvial material that have been abandoned and partly notched onto the slope of the mountain range (Figure 4). These alluvial remnants have been labeled upward from T_3 to T_8 with respect to the present-day streambed. From T_3 to the HAU, the surface morphologies consist of deflated stony desert pavements with rare boulders, relatively more frequent cobbles, and well-developed dark rock varnish. Actually, besides the higher degree of dissection characterizing the HAU with respect to the regional T_2 , nothing much is left on these surfaces to help distinguish them except their respective topographic position relative to the present-day streambeds. Another important observation is that the HAU apparently connects laterally to the mountain range, making it a probable equivalent of the preserved alluvial remnant T_7 (Figure 4).

To precisely define the chronological framework of this series of alluvial units, we measured the cosmogenic in situ-produced ^{10}Be concentrations within boulders and cobbles sampled from the surface of the alluvial T_2 and the HAU, as well as from the alluvial remnants T_6 and T_8 . From the alluvial terrace T_2 , four quartzite boulders (PDP41, PDP42, PDP62, and PDP63) and one quartz vein cobble (PDP43) were analyzed (Table 1). Except for the smallest quartz vein cobble, which shows a significantly younger minimum CRE age, all the analyzed boulders agree with an abandonment at roughly 30 ka (Table 1). For these four samples, the weighted mean is 31 ± 3 ka (Figure 4). Even if it cannot be strictly discarded from a statistical point of view, the boulder PDP63 is slightly older, maybe due to some ^{10}Be content inherited from previous exposure(s) before its deposition. Excluding PDP43 from the data set (low outlier), and bootstrapping the other CRE ages allows tuning down the contribution of sample PDP63, yielding a mean value of 31 ± 2 ka (Figure 4). From the HAU, two quartz vein boulders (PDP28 and PDP29) and one quartz vein cobble (PDP31) were analyzed and all agree on a weighted mean value of 120 ± 12 ka (Figure 4). Within these three samples, PDP29 seems slightly younger than the others even if it cannot be excluded from a statistical point of view. Bootstrapping this data population allows tuning down its contribution, yielding a mean value of 132 ± 15 ka (Figure 4). From the alluvial remnant T_6 , we analyzed two quartz vein boulders (PDP37 and PDP38), one granitoid boulder (PDP39), and one quartz vein cobble (PDP56). This last sample exhibits a significantly higher minimum CRE age of 191 ± 32 ka, probably due to some ^{10}Be content inherited from previous exposure(s) before its deposition, whereas the other three samples agree on an abandonment age at roughly 90 ka, with a weighted mean of 87 ± 9 ka and a bootstrap mean of 90 ± 10 ka (Figure 4). From the alluvial terrace T_8 , two quartz vein boulders (PDP34 and PDP35) exhibit consistent minimum CRE ages of 78 ± 13 and 73 ± 13 ka, respectively (Table 1).

The CRE ages obtained for these different alluvial terraces are relatively consistent and increase with the topographic position of the terraces above the streambed, with the exception of the alluvial remnant T_8 . Considering the bootstrapped central values of our groups of minimum CRE ages, the alluvial terrace T_2 was abandoned at 31 ± 2 ka, while the HAU and the alluvial remnant T_6 were abandoned at 133 ± 15 ka and 90 ± 10 ka, respectively. The younger CRE age derived from the alluvial remnant T_8 compared to that of T_6 is

not surprising. This highest alluvial remnant is poorly preserved with rare boulders and cobbles and has probably been reworked by postabandonment processes and/or contaminated by cobbles and boulders derived from the surrounding bedrock. Indeed, if the correlation of the HAU with T_7 is correct, then T_8 should be older than 133 ka.

At the outlet of Quebrada Niquizanga, we performed a detailed topographic survey to determine the amount of vertical incision with respect to the present-day streambed (Figure 4). From this data set, the present-day streambed is incised 10 m and 45 m below T_2 and T_6 , respectively. Considering that T_2 and T_6 were abandoned at 31 ± 2 ka and 90 ± 10 ka, respectively, these incision values imply rates of 0.3 ± 0.2 mm/yr and 0.5 ± 0.1 mm/yr (Figure 4). The HAU is hanging roughly 50 m above the present-day streambed, which implies an incision rate of 0.4 ± 0.1 mm/yr since it was abandoned at 133 ± 15 ka (Figure 4). All together, these estimates agree within their uncertainties, suggesting a fairly constant incision rate through time, with a mean value of 0.4 ± 0.1 mm/yr ($R^2 = 0.95$) (Figure 4). Assuming such a constant incision rate allows us to establish a tentative chronological framework for the abandonment of the levels identified as T_3 , T_4 , T_5 , T_7 , and T_8 at 53 ± 4 , 66 ± 5 , 83 ± 6 , 126 ± 10 , and 160 ± 13 ka, respectively (Figure 4). The 35 m elevation difference between the surfaces of T_2 and T_6 can be regarded as a proxy for surface uplift during the time span between their respective abandonments, which is over 60 ± 7 ka. These elevation and time differences lead to a surface uplift rate of 0.6 ± 0.1 mm/yr.

In summary, along the southeastern border of the SPDP, the landscape evolution seems to be a direct response to the progressive exhumation of the basement above the buried EPF fault, with an incision of the stream networks at a relatively constant rate of 0.4 ± 0.1 mm/yr. Even if the precise geometry of the EPF is still speculative at depth, the projection of a minimum incision rate of 0.3 mm/yr on a reverse fault plane dipping between 45 and 60° suggests a minimum fault slip rate of 0.4–0.6 mm/yr, which is a lower bound because fluvial incision might not have reached equilibrium. The upper bound of the incision rate, together with the 0.6 ± 0.1 mm/yr surface uplift rate determined from the differential elevation between T_2 and T_6 , suggest the possibility for higher fault slip rates of 0.4–1.2 mm/yr.

5.2. Rates of Vertical Incision and Surface Uplift (Northern Flank of SPDP, Agua Brava)

At Agua Brava, along the northeastern corner of the SPDP (Figures 5 and 6), the alluvial materials form thin (<3 m) sedimentary deposits that skirt the mountain piedmont, unconformably overlying the Neogene foreland strata exposed in incised banks along the stream network. These alluvial terraces can be arranged into four generations based on their topographic positions with respect to present-day streambeds (T_0) and are labeled, from younger to older, T_1 to T_4 (Figure 5). First, the dissection degree of the different alluvial units increases with their relative topographic positions (Figure 5). Alluvial terrace T_1 has a well-preserved surface morphology with bars and swales formed by abraded boulders and subangular cobbles and obvious rill-wash features. Relative to the topographic positions, the other alluvial terraces are characterized by diminishing preservation of streambed features together with increasing development of desert pavement and dark rock varnish as well as lack of large boulders. Among the alluvial generations that skirt the piedmont, the three younger ones (T_1 , T_2 , and T_3) are clearly affected by fault activity, showing increasing escarpment heights with relative age of the alluvial terraces (Figure 6).

To constrain the chronology of the terrace abandonment, we sampled well-preserved cobbles and boulders from atop the alluvial terraces T_1 , T_2 , and T_3 (Figure 5), avoiding areas close to terrace risers or incised gullies. Regarding alluvial terrace T_3 , we sampled the best preserved upstream part of the surface to prevent any complication due to postabandonment processes (Figure 5). The sampling was also performed on both sides of the mainstream to verify isochronicity of the surface (Figure 5). The sample population comprises two boulders of dark quartzite (PDP79 and PDP81), one cobble of quartzite (PDP87), one quartz vein cobble (PDP85), and one amalgam of quartz vein pebbles (PDP80). Within their uncertainties, all the samples delivered consistent minimum CRE ages and yield a weighted mean age of 41 ± 3 ka. Among these samples, the quartz vein cobble and the amalgam of quartz vein pebbles lead to minimum CRE ages that seem slightly older than the rest of the population (Table 1). For this group of samples, the bootstrap calculation of the mean value yields 43 ± 3 ka for the T_3 terrace (Figure 6).

On top of terrace T_2 , we sampled one gneiss boulder (PDP75), two quartzite boulders (PDP76 and PDP78), and one quartz vein cobble (PDP77). Both minimum CRE ages determined for PDP75 and PDP76 agree within their uncertainties, their mean value being 30 ± 4 ka. The quartz vein cobble yielded a much older minimum CRE age of 266 ± 44 ka. Conversely, one of the quartzite boulders (PDP78) delivered a much younger minimum

Figure 6. Agua Brava area (continued). (a) Topographic profiles parallel to the fault (Profiles 1 to 3) and topographic profiles orthogonal to the fault (Profiles 4 and 5). (b) Statistical analysis of CRE ages obtained for the alluvial units (T_1 , T_2 , and T_3). For each group of samples, outliers are identified (*); weighted mean (wm) and bootstrap mean (bs) are shown in the form of probability function plots (see also supporting information and section 3). (c) Vertical rates of incision (up) and surface uplift (down) derived from the combination of surface dating and topographic survey.

CRE age of 17 ± 3 ka. The most obvious interpretation regarding the quartz vein cobble PDP77 is that it bears a significant amount of cosmogenic ^{10}Be acquired during previous exposure(s) before its deposition on alluvial T_2 . Regarding PDP78, no clear evidence for postabandonment disturbance was noted in the field. The young age might thus result either from unrecognized postabandonment processes or overbank flooding during Late Glacial Maximum. Without further constraints, we bootstrapped the data population, excluding PDP77, to estimate a conservative mean value of 26 ± 3 ka for terrace T_2 abandonment (Figure 6).

On top of terrace T_1 , we sampled one gneiss boulder (PDP71) and three granitoid boulders (PDP70, PDP72, and PDP74). Two samples (PDP71 and PDP74) agree with a CRE age of 7 ± 1 ka, whereas the other two samples are significantly older, yielding minimum CRE ages of 25 ± 5 ka (PDP70) and 14 ± 2 ka (PDP72). One sample (PDP74) was taken on the surface downstream from the topographic escarpment, whereas the other three samples were taken from above it. Thus, one cannot argue that the youngest CRE ages are due to boulders previously shielded and reworked from the degradation of the topographic escarpment. One possible interpretation is that the two older boulders are reworked from alluvial materials cannibalized by the alluvium capping alluvial T_1 during its deposition. Indeed, the minimum CRE ages associated with the samples PDP70 and PDP72 are close to those of the samples measured on T_2 top. Given the observed dispersion of the minimum CRE ages, we considered that abandonment age for the alluvial T_1 can be bracketed between a lower

bound given by the youngest CRE ages (7 ± 1 ka) and an upper bound given by the bootstrapped central value of the whole data population (14 ± 3 ka), which is between 6 and 17 ka.

Using the topographic data acquired in the field (Figure 5), we determined incision values of the present-day streambed along three profiles that are located 150 m (Figure 6, profile 1), 300 m (Figure 6, profile 2), and 500 m (Figure 6, profile 3) upstream of the topographic escarpment. The vertical incision of T_0 with respect to alluvial terraces T_3 and T_2 increases upstream from 12 to 19 m and from 8 to 13 m, respectively (Figure 6). Integrated over the last 43 ± 3 ka and 26 ± 3 ka, these measurements yield vertical incision rates of 0.4 ± 0.1 mm/yr, which are similar to those determined at Niquizanga. Upstream of the topographic escarpment, the alluvial terrace T_1 is roughly 5 m above the present-day streambed (Figure 6). Considering the fairly large bracketing of terrace T_1 abandonment (6–17 ka), this height implies an incision rate ranging from 0.3 to 0.8 mm/yr.

To determine the topographic height of the escarpment affecting the alluvial terraces T_3 and T_2 , we extracted long profiles from the topographic data acquired in the field (Figure 5). The profile for terrace T_3 crosses well-preserved remnants on both the footwall and the hanging wall and indicates a vertical offset of 27 ± 2 m (Figure 6, profile 4). The profile for terrace T_2 indicates a vertical offset of 13 ± 1 m (Figure 6, profile 5). Along the same profile, the escarpment for T_3 is smaller (19 ± 1 m) than that measured on profile 4. However, given that (1) the topographic escarpment tends to diminish toward the eastern tip of the fault, and (2) terrace T_3 is covered and probably partially eroded by terrace T_2 downstream of the escarpment, this lower height is consistent with that determined using the profile to the west. When combined with the CRE abandonment ages discussed above, the topographic heights determined for T_2 and T_3 lead to surface uplift rates of 0.5 ± 0.1 and 0.6 ± 0.1 mm/yr, respectively (Figure 6). The alluvial surface T_1 is offset 3 m by the Pajaritos Fault (Figure 6). Considering the fairly large bracketing of terrace T_1 abandonment (6–17 ka), this height implies a surface uplift rate ranging from approximately 0.2 to 0.5 mm/yr.

In summary, local uplift rates estimated from the escarpment heights are similar for terraces T_2 and T_3 (over the last 23–46 ka), while the rate seems slightly slower for terrace T_1 (over the last 6–17 ka). This discrepancy might result from an incomplete upward propagation of coseismic surface ruptures through the very coarse torrential material, which is mainly made of boulders, and/or an insufficiently long time window with respect to the seismic cycle, particularly if a mid-Holocene age is considered. This latter possibility is also suggested by the absence of an obvious knickpoint affecting the streambed profile. Both possibilities may result in a surface displacement deficit for terrace T_1 . Finally, assuming a simple pure reverse movement on the Pajaritos Fault dipping at (50 – 60°), a minimum slip rate of 1.0 ± 0.4 mm/yr can be calculated over the last 23 to 46 ka and of 0.6 ± 0.4 mm/yr for the period postdating terrace T_1 abandonment (6–17 ka).

5.3. Denudation Rates

To determine denudation rates, we sampled bedrock outcrops located close to the SPDP summit (Cerro Mogote, 3162 m) and along the southeastern border of the range at Niquizanga (Figure 7). The samples comprise quartzite, gneiss, and quartz veins that correspond to the erosional envelope of the fold. The only exception is sample PDP3, which consisted of an amalgam of quartz vein pebbles scattered around the sampling site of PDP2. The measured ^{10}Be concentrations of samples PDP2, PDP3, and PDP4 samples correspond to maximum denudation rates of 4 ± 1 , 6 ± 1 , and 11 ± 2 m/Ma, respectively (Table 1). At Niquizanga, the bedrock samples (PDP12a, PDP14a, and PDP50) yielded similar maximum denudation rates ranging from 3.0 ± 0.5 to 5 ± 1 m/Ma. The MSWD analysis identified sample PDP4 as a high outlier with respect to the other bedrock samples (Figure 7). This sample was taken from a patch of bedrock hardly outcropping at the surface, close to the antenna of the meteorological station of Mogote, and may have been affected by more locally active surface processes. With the exception of PDP4, all the bedrock samples converge toward maximum bedrock denudation rates of 4–5 m/Ma. Bootstrapping all the data but PDP4 also yields a central value of 4.5 ± 0.4 m/Ma (Figure 7), which can be regarded as a conservative estimate of maximum denudation rates affecting the bedrock in the area of the SPDP.

To determine spatially integrated denudation rates, we sampled modern river-borne sediments at the outlets of four watersheds draining the SPDP. Sample PDP10 corresponds to the Quebrada Salinas Grandes watershed, the largest one draining the SPDP to the west, which developed within the Grande El Molle fault zone (Figure 1). Along the northern border, we sampled two watersheds in the area of Agua Brava (PDP20 and PDP84). Along the southeastern border, we sampled the outlet of the quebrada draining the SPDP at Niquizanga (PDP32). The catchment-wide denudation rates are 65 ± 11 m/Ma (PDP10), 42 ± 7 m/Ma (PDP32), 110 ± 25 m/Ma (PDP20), and 109 ± 18 m/Ma (PDP84) (Table 1). As such, it appears that catchment-wide

Figure 7. Cosmogenic nuclide-derived denudation rates for Sierra Pie de Palo. (a) Landsat image of the SPDP locating (1) the two bedrock sampling sites (blue solid circles) at Cerro Mogote (3162 m) on top of the surface and at Niquizanga on the southeastern flank of the range, respectively, and (2) the watershed outlets where river-borne sands were sampled (red solid circles, watersheds are highlighted in light red). (b) Field photographs of the sampling site at Cerro Mogote (upper left: PDP2-3; upper right: PDP4) and Niquizanga (lower left: PDP12a; lower right: PDP14a). (c) Statistical analysis of denudation rates obtained for the bedrock samples. Outliers are identified (asterisk); weighted mean (wm) and bootstrap mean (bs) are shown in form of probability function plots (see also supporting information and section 3).

denudation rates could be as much as 30 times higher than bedrock denudation rates. Located along the active northern border of the SPDP, samples PDP20 and PDP84 exhibit the highest catchment-wide denudation rates, which is not surprising because their watersheds are more likely to be more rapidly uplifted. When compared to PDP84 and PDP20, sample PDP10 exhibits a catchment-wide denudation rate that is roughly 30% lower. Another interesting feature is that northern watersheds' catchment-wide denudation rates are apparently not different, whereas the watershed of PDP84 is roughly 4 times larger than that of PDP20 (Table 2). Finally, located along the southeastern border of the SPDP, sample PDP32 exhibits the lowest catchment-wide denudation rate. The difference between the high catchment-wide denudation rates determined along the northern border and that of the PDP32 watershed along the southeastern border might well reflect a difference in tectonic activity between the two areas.

Table 2. Excavation Times Estimated From Cosmogenic Nuclide-Derived Denudation Rates (Measured Watersheds)^a

	Volume (Surf-SRTM) (km ³)	Area (km ²)	Ratio V/S (km)	Denudation (m/Ma)		Excavation Time (Myr)	
				Value	Error	Value	Error
PDP10	15.9	82.7	0.19	65	11	3.0	0.5
PDP20	0.2	2.5	0.08	110	25	0.7	0.2
PDP32	0.4	10.0	0.04	42	7	0.9	0.1
PDP84	1.2	13.7	0.09	109	18	0.8	0.1

^aMinimum eroded volumes are estimated subtracting the present-day topography (SRTM DEM) to the surface envelope model (Figure 2) according to *Champagnac et al.* [2014]. Watershed areas have been extracted from the digital elevation model (SRTM DEM) using RivertoolsTM software. Denudation rates correspond to cosmogenic nuclide-derived estimates, and excavation times are determined assuming that denudation rates are constant with time.

5.4. Influence of Denudation Rates on Inferred Tectonic Rates

In situ-produced ¹⁰Be concentrations measured in boulders or cobbles deposited onto the surface of alluvial terraces have been interpreted as minimum exposure ages assuming rapid exposure and no burial or erosion after the beginning of the exposure. As described in sections 5.1 and 5.2, most of the studied alluvial surfaces exhibit the characteristics of deflated stony desert pavements through winnowing with well-developed desert varnish. If the sampled boulders were deposited at the surface of the alluvial terraces during the last alluviation episode before abandonment, they should have remained fully exposed to cosmic rays, even during surface lowering through deflation of the fine materials and compaction of the alluvial material. The denudation rates of about 4–6 m/Ma derived by *Hedrick et al.* [2013] from two cosmogenic concentration depth profiles within alluvial materials in the Eastern Precordillera actually estimate such a surface lowering rate. Within this context, the denudation processes affecting the exposed boulders themselves should still be regarded as negligible. However, if a denudation rate of about 4–6 m/Ma is considered to be active on the boulders themselves, then those showing CRE ages of roughly 30 ka should be roughly 10% older, those with CRE ages of 40–60 ka should be roughly 15–20% older, and those with CRE ages older than 70–90 ka should be 30–40% older. Under such an assumption, the samples showing CRE ages older than ≈140 ka appear saturated from the cosmogenic nuclide production point of view (see supporting information). Finally, the tectonic rates should be lowered by a factor of about 15% under the assumption that a denudation rate of roughly 5 m/Ma applies to the cobbles and boulders themselves.

6. Discussion

6.1. The Pampean Paradox

In the western SP, there is a paradox between the lack of Cenozoic cooling ages and the structural reconstructions and basin analyses that suggest several kilometers of exhumation [*Dávila and Carter*, 2013]. Neogene to Quaternary evidence for tectonic activity associated with the Pampean thrusts is described by *Costa et al.* [2000], *Ramos et al.* [2002], *Richardson et al.* [2013], and this study. For example, to the north of the NPF, the first 10 km below the surface corresponds to the Neogene units of the Bermejo foreland basin [*Zapata*, 1998]. Therefore, there is a maximum structural relief of about 13 km, assuming that the summit of SPDP was at the same topographic datum as the bottom of the Bermejo basin at the beginning of the Neogene sedimentation [*Smalley et al.*, 1993].

On the other hand, the exhumation of the Pampean ranges have long been studied using multiple thermochronometric methods, including apatite and zircon fission tracks, (U-Th)/He, and zircon U-Pb [*Jordan et al.*, 1989; *Coughlin et al.*, 1998; *Sobel and Strecker*, 2003; *Carrapa et al.*, 2008; *Löbens et al.*, 2011, 2013a, 2013b; *Enkelmann et al.*, 2014]. In the westernmost SP, no Cenozoic cooling ages have been reported [*Jordan et al.*, 1989; *Coughlin et al.*, 1998; *Löbens et al.*, 2011, 2013b], contrasting with the northern Pampean ranges, where the most recent exhumation episode started during the Miocene and the Pliocene [*Sobel and Strecker*, 2003; *Carrapa et al.*, 2008]. In the case of the SPDP, *Löbens et al.* [2013b] used apatite fission track data and (U-Th)/He measurements of zircon and apatite and proposed that its final cooling and exhumation possibly started

60 Ma ago in relation with the denudation of a positive topography already existing since the Mesozoic. This most probably reflects that the thermochronological data are insensitive to the most recent phase of relief development in this Andean region.

6.2. Testing the Pampean Paradox

The cosmogenic-derived results presented in this study allow constraining the uplift scenario experienced by the SPDP. Indeed, subtracting the present-day topography (SRTM90 DEM) from the fold envelope (Figure 2) allows estimating the minimum volume of rock eroded since the bedrock was uplifted (geophysical relief [e.g., *Champagnac et al.*, 2014]). Assuming that the development of the watersheds has started as soon as the Precambrian rocks reached the surface (once overlying Neogene strata were eroded), durations needed to excavate the eroded volumes can be roughly estimated for each studied watershed assuming constant denudation rates through time (Table 2).

Whether denudation rates integrated over the last 10–100 kyr (this study) can be propagated over much longer periods of time is an important issue. Considering that widespread increases in sediment accumulation have been described at the onset of Quaternary glaciations [*Hay et al.*, 1988; *Molnar and England*, 1990; *Métivier et al.*, 2002; *Molnar*, 2004; *Zhang et al.*, 2001; *Herman et al.*, 2013], changes in denudation rates at million year timescales are poorly constrained, and their Plio-Quaternary variability at the global scale is still a matter of debate [*Willenbring and von Blanckenburg*, 2010; *Puchol et al.*, 2012]. For example, *Hidy et al.* [2014] showed the low-relief, nonglaciated, and tectonically inactive landscape of interior of Texas to erode more rapidly (30–35% increase) during interglacial periods in connection with higher temperatures. However, since Plio-Quaternary variability of denudation rates in this Andean region is still unknown, we made the oversimplified assumption that catchment-wide and bedrock cosmogenic-derived denudation rates can be extended over the past few millions of years.

Assuming this simplistic scenario, the time needed to excavate the largest studied watershed (sample PDP10; Quebrada Salinas Grandes) is estimated at 3.0 ± 0.5 Ma (Table 2). Interestingly, for both northern and eastern sides of the range, the minimum eroded volumes combined with the catchment-wide denudation rates yield comparable excavation durations of about 1 Ma (Table 2). This link between catchment-wide denudation rates, excavation durations, and drainage basin development can be illustrated by the linear relationship between excavation durations and watershed areas (Figure 8a). Our bedrock samples indicate that up to 4.5 ± 0.4 m/Ma of material was lost by the uplifting bedrock surface, leading to as much as 10 to 18 m of surface lowering during the last 3.0 ± 0.5 Ma. When integrated over the range, this surface lowering represents approximately 2.4–4.3 km³ and thus only 2 to 3% of the total 135 km³ minimum eroded volume excavated by fluvial erosion (Figure 2). This estimate led us to consider that the minimum eroded volume determined from the geophysical relief is relatively close to the actual volume of eroded material.

Slope is often considered as one of the main controlling parameters in erosion models [e.g., *Champagnac et al.*, 2014, and references therein]. Despite the limited number of measurements available for the SPDP, the catchment-wide denudation rates increase nonlinearly with slope up to values of roughly 110 m/Ma corresponding to an average basin slope of roughly 23° (Figure 8b). The catchment corresponding to sample PDP20 has a higher average slope (28°), whereas its catchment-wide denudation rate is also of about 110 m/Ma. However, the drainage area of this particular watershed is very small with respect to the other studied basins and should not be characterized by sufficient sediment mixing as required to meet with the method's assumptions. Sample PDP20 can thus be regarded as an outlier and discarded from the exponential relationship linking catchment-wide denudation with basin average slope (Figure 8b). Interestingly, the significantly lower maximum denudation rates determined for bedrock outcrops with slopes of 8–10° are in good agreement with this relationship. This threshold above which denudation no longer scales with slope [e.g., *Montgomery and Brandon*, 2002; *Ouimet et al.*, 2009] has been described in California [*DiBiase et al.*, 2010], Central Chile [*Carretier et al.*, 2012], and Qilian Shan [*Palumbo et al.*, 2011].

The exponential relationship can be used to model catchment-wide denudation rates from the regional pattern of average basin slope (Figures 8c and 8d). This operation unveils that most of the watersheds with the highest modeled catchment-wide denudation rates are distributed along the northern and eastern flanks of the SPDP where the master active faults are located (Figure 8e). Therefore, slope, and hence tectonic activity, appears to be the main parameter controlling fluvial-driven erosional and denudation processes in the desert environment of this Andean region.

Figure 8. Regional pattern of excavation durations for the Sierra Pie de Palo. (a) Plot diagram showing the linear relationship between excavation durations (determined from cosmogenic nuclide-derived denudation rates and minimum eroded volumes) and watershed areas. (b) Plot diagrams showing the exponential relationship linking denudation rate and the watershed average slope (calculated over the basin area around the sample pixel). (c) Regional pattern of watershed slope averaged over drainage basin area. (d) Minimum eroded volumes determined for each watershed from the spatial integration of vertical incision values (Figure 2e). (e) Denudation rates modeled from the slope-denudation relationship (shown in Figure 8b). (f) Regional pattern of excavation durations derived from the combination of modeled denudation rates (shown in Figure 8e) with minimum eroded volumes for each watershed (shown in Figure 8d).

Combining the regional patterns of denudation rates and the minimum eroded volumes allows us to estimate the durations needed to excavate the largest watersheds at approximately 4 Ma (Figure 8f). However, this first-order estimate should be revised in the future once actual denudation rates characterizing the Early Quaternary and the Pliocene are made available. In addition, accounting for the excavation durations calculated for the studied watersheds (Table 2) and those modeled using the exponential relationship that links

Figure 9. Longitudinal topographic profiles for selected river channels incised into the Sierra Pie de Palo. (a) Map of the SPDP showing the location of the selected river channels (numbered 1 to 5). Numbers give the elevation (in meters) of the headwaters and outlets for selected river channels. (b) Plot diagrams showing the longitudinal topographic profiles of the selected river channels extracted from the SRTM90 DEM using Rivertools software.

denudation and average slope suggest a more recent phase of topographic rejuvenation at roughly 1–2 Ma, which could be related to the development of the steeper northern and eastern flanks of the SPDP anticline.

Because cosmogenic-derived denudation rates and eroded volumes are maximum and minimum estimates, respectively, when combined to assess watershed excavation durations, they lead to lower limits. Furthermore, river systems respond transiently to an increase in uplift rate, the hillslope response being delayed after the transient knickpoint has moved upstream and passed over the hillslope base level. Such river adjustment, where the incision rate matches the background uplift rate, can be described by a simple scaling relationship between the upstream change in the channel elevation (Δz) from either a knickpoint, if the riverbed is still in a transient state, or from the outlet, if it is fully adjusted [Whipple, 2010; Schildgen *et al.*, 2012]:

$$\Delta z = \Delta t \cdot (U_f - U_i) \quad (1)$$

where Δt is the time elapsed since the change of uplift, U_f is the final uplift rate, and U_i is the initial uplift rate. Because the vertical accuracy of SRTM DEM is at best on the order of several meters (≤ 15 –20 m) [e.g., Gorokhovitch and Voustianiouk, 2006; Czubski *et al.*, 2013], this relationship was only explored along the major river channels incised into the SPDP. Selected longitudinal topographic profiles do not evidence obvious and significant knickpoints along the course of the river channels (Figure 9), suggesting that these major rivers may have reach equilibrium. The elevation differences measured between headwaters and outlets (Δz) range from 1390 to 1900 m (Figure 9). Constraining the final uplift (U_f) between a lower bound based on the cosmogenic-derived incision rate (0.4 ± 0.1 mm/yr) and an upper bound based on the cosmogenic-derived surface uplift rates (0.5 ± 0.2 mm/yr), and assuming a negligible initial uplift (U_i), the scaling relationship proposed by Whipple [2010] lead to a maximum time elapsed since the beginning of the uplift comprised between 2 and 6 Ma. The minimum time durations required to erode the incised volumes estimated from denudation rates may therefore be doubled if transient changes of the watersheds during the uplift must be taken into account.

6.3. Long-Term, Geomorphic, and Short-Term Tectonic Rates

The scenario described above favors the hypothesis that the onset of the present-day topography should have occurred during the Pliocene, possibly at 4–6 Ma, providing far greater resolution into the recent landscape evolution than has been possible with thermochronological data [Löbens *et al.*, 2013b]. Actually, Dávila and Carter [2013] proposed that previous interpretation of thermochronological data underestimated the magnitude of rock uplift and exhumation of the Pampean blocks by neglecting the thermal effects of flat slab subduction, which may have substantially depressed the geothermal gradient by removing the mantle wedge [e.g., Collo *et al.*, 2011], and shortened exposure to heating due to rapid Neogene burial and

subsequent Andean uplift. The relatively deep, ≈ 35 km seismogenic depth below the westernmost SP [Régner *et al.*, 1992; Smalley *et al.*, 1993] is also in quite good agreement with a depressed geothermal gradient [Alvarado *et al.*, 2009].

Using a geothermal gradient of $18\text{--}23^\circ\text{C}/\text{km}$ [e.g., Dávila and Carter, 2013] and a paleosurface temperature of 17°C [e.g., Löbens *et al.*, 2013b] implies that an exhumation of 1.9–2.4 km is needed to bring rock cooling from below 60°C to the surface. This thickness may represent the Neogene foreland strata that might have covered the SPDP basement [Ramos and Vujovich, 2000; Ramos *et al.*, 2002]. Once the sediment cover was eroded, the basement rocks started experiencing denudation and drainage network development. According to the cosmogenic nuclide-derived denudation rates combined with the minimum eroded volume estimates, this last process may have started at about 4–6 Ma. Buckling of the crust below the SPDP probably started with the inception of rapid exhumation of the basement in the Sierra Valle Fértil system at 10 Ma [Coughlin *et al.*, 1998]. Thus, exhumation of the basement rocks from 1.9–2.4 km to the surface should have taken place during a time span of about 4–6 Ma, leading to an exhumation rate of about 0.3–0.6 mm/yr, which is roughly 10 times faster than that integrated by Löbens *et al.* [2013b] over the last 60 Ma. As the top of SPDP is presently at an elevation of roughly 3.2 km, towering over a plain standing at 600 m, this also implies a rock uplift of 4.5 to 5.0 km to be accommodated over the last 10 Ma and thus leads to a long-term uplift rate of approximately 0.5 mm/yr. Over the last 4–6 Ma, 2.6 km of rock uplift should have been accommodated at a rate of about 0.4–0.7 mm/yr. Long-term rock uplift rates estimated over the last 10 to 4 Ma are in good agreement with the surface uplift and incision rates that have been determined on geomorphic time scales at Agua Brava and Niquizanga using offset geomorphic markers and CRE dating.

In this Andean region, Brooks *et al.* [2003] proposed a craton-fixed velocity field from survey and continuous GPS networks spanning from 1993 to 2001. At a first order, this velocity field is dominated by the elastic loading of the locked subduction interface, with the largest velocities (35 mm/yr) being closer to the trench and decreasing cratonward. This GPS study also suggests a possible decrease of the present-day velocities with a maximum of some 5 mm/yr to be accommodated by the active faults located between the Eastern Pre-cordillera and Sierra de Valle Fértil. In the Eastern AP, structural and geochronological studies concluded that the Holocene shortening rate associated with the Villicum-Perdernal Fault should be about 1 mm/yr [Siame *et al.*, 2002; Meigs *et al.*, 2006], comparable with the one derived from a paleoseismic study in the Tullum Valley [Rockwell *et al.*, 2014]. As the deformation rates for the SPDP based on offset geomorphic markers along individual faults are also approximately 1 mm/yr, GPS-derived velocities are thus in good agreement with the tectonic rates integrated over Holocene to Pleistocene time scales.

7. Conclusions

In the westernmost SP, the SPDP concentrates most of the regional seismic moment release and plays a key role in the structural evolution of the Andean foreland of northwestern Argentina. In this region, measurement of in situ-produced cosmogenic ^{10}Be concentrations allows us to quantitatively constrain the landscape evolution during the Plio-Quaternary in connection with active tectonics linked to mountain building processes and the growth of a large basement anticline. Using a combination of CRE dating of stepped and/or faulted alluvial landforms and detailed topographic analyses, we estimated incision and uplift rates along its major bounding faults.

Along the southeastern border of the SPDP, progressive exhumation of the regional erosion surface combined with climate-driven alluvial deposition constructed a series of stepped alluvial terraces that were abandoned between 31 ± 3 ka and 132 ± 15 ka. With this new chronological framework, we estimated a minimum slip rate for the EPF of 0.5 ± 0.1 mm/yr, with the possibility of a faster rate of 0.8 ± 0.4 mm/yr. Along the northern border of the SPDP, the Pajaritos Fault affects a series of alluvial terraces, producing topographic escarpments. Combining CRE dating of the deformed alluvial landforms with topographic measurements of these fault escarpments, we determined a Pleistocene fault slip rate of 1.0 ± 0.4 mm/yr, with the possibility of a slower Holocene slip rate of 0.6 ± 0.4 mm/yr. The fault slip rates estimated for Holocene to Pleistocene time scales are in good agreement with the 0.5–1 mm/yr rate estimated over the last 10 Ma [Zapata and Allmendinger, 1996; Zapata, 1998; Ramos *et al.*, 2002] and compatible with the GPS-derived velocity field [Brooks *et al.*, 2003].

Catchment-wide, cosmogenic nuclide-derived denudation rates combined with watershed geomorphic characteristics allows us to estimate the time span for the development of the river network incising the uplifted and folded erosional surface. In our scenario, 1.9 to 2.4 km exhumation of the SPDP basement has taken

place from 10 to 4–6 Ma, in connection with the westward propagation of the SP and inception of the Eastern AP. This exhumation led the basement rocks to reach the surface at about 4–6 Ma, implying a Pliocene onset of the development of present-day relief. In addition, the SPDP anticline experienced a flank steepening episode above the two major bounding NPF and EPF structures at roughly 1–2 Ma, resulting in the observed geomorphic rejuvenation and asymmetric, arched morphology.

Large earthquakes such as the M_w 7.4, 1977 Cauçete event may produce average coseismic displacements of roughly 1.6 to 2.2 m on a 65 km long fault dipping between 50 and 60°. Assuming a simplistic pure stick-slip fault behavior and accounting for a fault slip rate ranging from 0.6 to 1 mm/yr, the recurrence interval for such large earthquakes should be of approximately 2000–4000 years, i.e., similar to that calculated from paleoseismic data for the M_w 7.4 1944 San Juan event in the Eastern Precordillera [Rockwell *et al.*, 2014]. Finally, from a regional point of view, active deformation between the eastern front of the Central AP and the SP is thus located on the western edge of the Tulum valley, the SPDP, and the Las Chacras Fault at the toe of the Valle Fértil Fault system.
