ABSTRACT

The RecBCD complex is a key factor in DNA metabolism. This protein complex harbors a processive nuclease and two helicases activities that give it the ability to process duplex DNA ends. These enzymatic activities make RecBCD a major player in double strand break repair, conjugational recombination and degradation of linear DNA. In this work, we unravel a new role of the RecBCD complex in the processing of DNA single-strand gaps that are generated at DNA replication-blocking lesions. We show that independently of its nuclease or helicase activities, the entire RecBCD complex is required for recombinational repair of the gap and efficient translesion synthesis. Since none of the catalytic functions of RecBCD are required for those processes, we surmise that the complex acts as a structural element that stabilizes the blocked replication fork, allowing efficient DNA damage tolerance.

INTRODUCTION

Genomes of all living organisms are constantly damaged by endogenous and exogenous stresses. Despite efficient repair mechanisms, some DNA lesions can escape repair and block the replicative polymerase. In order to bypass these ‘roadblocks’ and complete replication, cells have developed two DNA Damage Tolerance (DDT) pathways identified both in prokaryotes and eukaryotes: (i) translesion synthesis (TLS), which employs specialized DNA polymerases in prokaryotes and eukaryotes: (i) translesion synthesis (TLS), which employs specialized DNA polymerases able to replicate damaged DNA, with the potential to introduce mutations (1); (ii) damage avoidance (DA) pathways (also named template switching), which use the information of the sister chromatid to bypass the lesion in a non-mutagenic way through homologous recombination mechanisms (2,3). While the TLS pathway has been well characterized in the past few years, little is still known about Damage Avoidance pathways.

We have recently developed a genetic tool that enables us to monitor in vivo the exchange of genetic information between sister chromatids (i.e. DA events), following the insertion of a single lesion into the chromosome of Escherichia coli (4). We showed that after encountering a replication-blocking lesion either on the lagging or the leading strand, the replication fork is able to restart downstream of the lesion, leaving a single strand gap. Filling of this gap (also termed ‘single strand gap repair’, SSG repair) can be achieved either by TLS, or, to a higher frequency, by a DA mechanism that we named ‘Homology Directed Gap Repair’ (HDGR). The HDGR pathway proved to be dependent on the bacterial recombinase RecA through the RecFOR pathway, already known to be involved in single strand gap repair (5–8). The major function of the RecFOR complex at a gapped DNA is to disassemble the filament of single strand binding protein (SSB) in order to load RecA and promote homologous recombination (9,10).

Interestingly, we also observed the participation of RecB in HDGR events (4,11). RecB is part of the RecBCD complex, which is the key enzyme for initiation of recombinational repair of double-strand breaks (DSB) (12), conjugational recombination (13) and for degradation of linear DNA (also known as ExoV) in E. coli (5,14). The RecBCD complex is composed of three distinct subunits (RecB, RecC and RecD) that together encompass several catalytic activities: DNA-dependent ATPase, DNA helicase, ssDNA endo and exonuclease, and dsDNA exonuclease. These activities enable RecBCD to be a potent and highly processive helicase and nuclease complex that processes duplex DNA ends and loads the recombinase RecA onto single-stranded DNA (ssDNA) during recombination events. The N-terminal regions of RecB and RecD contain a SF1 helicase motif (15), conferring a 3′→5′ and 5′→3′ helicase activity, respectively. This bipolar translocation is the basis for the characteristic velocity and processivity of RecBCD (it can unwind up to 30 kbp per binding event) (16,17). The C-terminal region of RecB contains the nuclease domain as well as the RecA interaction domain. A specific DNA sequence named Chi (5′-GCTGGTG-3′) regulates all the catalytic activities of RecBCD (reviewed in (5,14)). The function of RecC still needs to be completely elucidated, however recC mutants seem to point towards a role in Chi recognition (18,19).

Traditionally, the RecBCD complex has always been associated with the repair of double-strand breaks, while the RecFOR pathway was associated with the repair of single strand gaps formed upon replication fork stalling followed by re-priming downstream of the lesion (5,6). However, it has been shown that when part (or all) of the enzymatic machinery of RecBCD is affected, RecQ helicase and RecJ nuclease (that are part of the RecFOR pathway) can achieve the resection of DNA ends, while RecFOR loads RecA nucleofilament, allowing the cell to be completely proficient for DSB repair (20,21). In contrast, until our recent study, no evidence pointed towards a role for RecBCD in SSG repair. Indeed, we showed that inactivation of the recB gene leads to a decrease in HDGR events, even in the presence of a functional RecFOR pathway, suggesting that RecBCD does not act as a backup, but has its own contribution. To perform an efficient HDGR mechanism, both RecBCD and RecFOR complexes are necessary since the double mutant showed a phenotype similar to that of a recA mutant (i.e. an almost complete abolition of HDGR events). In the present work, we are further elucidating the role of RecBCD in the HDGR pathway. We demonstrate that the RecBCD complex is involved in SSG repair in a non-canonical way that is distinct from its DSB repair functions. Indeed, none of the characteristic enzymatic activities of RecBCD (i.e. nuclease, helicase and RecA-loading) are required for its participation to HDGR mechanisms. Furthermore, we find the TLS pathway to be strongly affected in the absence of RecBCD. We suggest that the RecBCD complex plays an unprecedented structural role in single strand gap repair that is necessary for both HDGR and TLS pathways.

MATERIALS AND METHODS

Bacterial strains and growth conditions

All E. coli strains used in this work are derivative of strains FBG151 and FBG152 (22,23) and are listed in Supplementary Table S1. Strains were grown on solid and in liquid Lysogeny Broth (LB) medium. Gene disruptions of recA, recF, recO, recB, recD, sulA, mutS and uvrA were achieved by the one-step PCR method (24). To obtain the recDK177Q strain, the recD gene has been first cloned into the pKD4 vector (24) digested by NdeI and then we performed site-specific mutagenesis to obtain the K177Q mutant (i.e. an almost complete abolition of HDGR events). In the present work, we are further elucidating the role of RecBCD in the HDGR pathway. We demonstrate that the RecBCD complex is involved in SSG repair in a non-canonical way that is distinct from its DSB repair functions. Indeed, none of the characteristic enzymatic activities of RecBCD (i.e. nuclease, helicase and RecA-loading) are required for its participation to HDGR mechanisms. Furthermore, we find the TLS pathway to be strongly affected in the absence of RecBCD. We suggest that the RecBCD complex plays an unprecedented structural role in single strand gap repair that is necessary for both HDGR and TLS pathways.

Plasmids

A list of all the plasmids used is this study is provided in Supplementary Table S2.

pVP135 expresses the integrase and excisionase (int–xis) genes from phage lambda under the control of a trc promoter that has been weakened by mutations in the −35 and the −10 region (26). Transcription from Ptrc is regulated by the lac repressor, supplied by a copy of lacIq on the plasmid. The vector has been modified as previously described (22), pKN13 is similar to pVP135 except that it possesses a chloramphenicol resistance gene instead of a kanamycin resistance gene.

pLL58 and pLL59 are derived from pKN13 and contain the recA gene or the recA730 allele, respectively, in continuity with the xis-int operon. The genes together with their ribosome-binding site have been cloned in pKN13, previously digested by HindIII and blunt ended.

pVP146 is derived from pACYC184 plasmid where the chloramphenicol resistance gene has been deleted by BsaAI digestion and re-ligation. This vector, which carries only the tetracycline resistance gene, serves as an internal control for transformation efficiency.

pVP141-144, pGP1, 2 and 9 are derived from pLDR9-attL-lacZ as described in (22). pLL1 and pLL2c are derived from pVP141 and contain several genetic markers as previously described (4). All these plasmid vectors contain the following characteristics: the ampicillin resistance gene, the R6K replication origin that allows plasmid replication only if the recipient strain carries the pir gene (27), and the S′ end of the lacZ gene in fusion with the attL site-specific recombination site of phage lambda. The P3′ site of attL has been mutated (AATTATTAT to AATTATTAT) to avoid the excision of the plasmid once integrated (28). These plasmids are produced in strain EC100D pir-116 (from Epicentre Biotechnologies, cat# EC6P0950H) in which the chloramphenicol resistance gene has been deleted by BsaAI digestion and re-ligation. This vector, which carries only the tetracycline resistance gene, serves as an internal control for transformation efficiency.

pVP141-144, pGP1, 2 and 9 are derived from pLDR9-attL-lacZ as described in (22). pLL1 and pLL2c are derived from pVP141 and contain several genetic markers as previously described (4). All these plasmid vectors contain the following characteristics: the ampicillin resistance gene, the R6K replication origin that allows plasmid replication only if the recipient strain carries the pir gene (27), and the S′ end of the lacZ gene in fusion with the attL site-specific recombination site of phage lambda. The P3′ site of attL has been mutated (AATTATTAT to AATTATTAT) to avoid the excision of the plasmid once integrated (28). These plasmids are produced in strain EC100D pir-116 (from Epicentre Biotechnologies, cat# EC6P0950H) in which the chloramphenicol resistance gene has been deleted by BsaAI digestion and re-ligation. This vector, which carries only the tetracycline resistance gene, serves as an internal control for transformation efficiency.
Monitoring HDGR and TLS

To 40 μl aliquot of competent cells, prepared as previously described (22), 1 ng of the lesion-carrying vector mixed with 1 ng of the internal standard (pVP146) was added and electroporated in a GenePulser Xcell from BioRad (2.5 kV, 25 μF, 200 Ω). Cells were first resuspended in super optimal broth with catalytic repressor (SOC), then diluted in LB containing 0.2 mM IPTG. Cells were incubated for 45 min at 37° C. Part of the cells were plated on LB + 10 μg/ml tetracycline to measure the transformation efficiency of plasmid pVP146, and the rest were plated on LB + 50 μg/ml ampicillin + 80 μg/ml X-gal to select for integrants (AmpR) and to visualize HDGR or TLS events (lacZ+ phenotype depending on the vector used). Cells were diluted and plated using the automatic serial diluter and plater EasySpiral Dilute (Interscience). Colonies were counted using the Scan 1200 automatic colony counter (Interscience). Integration rate, transformation efficiency and plating efficiency vary according to the genetic backgrounds. The integration rate is in the range of 2000 clones/pg of vector for our parental strain. For rec− strains whose viability is affected and plating efficiency reduced, this rate can drop to ∼200 clones/pg.

We plated before the first cell division; therefore, following the integration of the pLL1/2c vector, sectored blue/white colonies represent HDGR events; sectored pale blue/white colonies represent TLS events and pure white colonies represent damaged chromatid loss event (Figure 1). Following integration of the pVP141/142, pVP143/144, pGP1/2, pVP143/pGP9 vectors, sectored blue/white colonies represent TLS events. The relative integration efficiencies of lesion-carrying vectors compared with their lesion-free homologues, normalized by the transformation efficiency of pVP146 plasmid in the same electroporation experiment, allow the overall rate of lesion tolerance to be measured.

RESULTS

The nuclease domain of RecB is not required for HDGR mechanism

In order to assess the role played by the different subunits of RecBCD in HDGR, we used a genetic system that we previously developed (4). Briefly, a vector containing a single replication-blocking lesion is integrated in the bacterial chromosome by mean of the phage lambda integrase. The vector carries a combination of four genetic markers (Figure 1) that allows to directly visualize the exchange of genetic information between the damaged strand and the non-damaged sister chromatid. Using this assay, we previously showed that sister-strand exchange events (named Homology Directed Gap Repair) are the major DDT pathway. When cells fail to fill the ssDNA gap, they can still survive by replicating their non-damaged chromatid and losing the damaged one (4). We named these events ‘damaged chromatid loss’. We also showed that the HDGR pathway is dependent on the recombinase RecA, mainly through the RecFOR pathway and to a lesser extent through the action of RecB (Figure 2, and see (4)). The deletion of recB gene was indeed accompanied by a decrease in HDGR events of ∼30% when the lesion is located on the lagging strand, and ∼15% when on the leading strand (Figure 2 and (4)). When the HDGR pathway is affected, it can be compensated by an increase in damaged chromatid loss events, as we can clearly see in a recF− strain and to a lesser extent in the recB− strain (Figure 2). In some cases, a decrease in HDGR can also be accompanied by a decrease in survival, as in the recB− strain for the leading strand or in the recB recF double mutant (Figure 2). A loss of survival is attributed to the presence of unrepaired lesions on the opposite strand that prevents damaged chromatid loss to occur and leads to lethality (4). Since it is the first time that the RecBCD complex appears to be involved in single strand gap repair, we undertook to further explore its role in the HDGR mechanism.

In the present study, all experiments were conducted in a parental strain where mismatch repair (mutS) has been inactivated (to prevent corrections of the genetic markers), as well as nucleotide excision repair (uvrA), to avoid excision of the lesion and to focus on lesion tolerance events. To measure HDGR events, we used the UV-induced thymine-thymine pyrimidine(6-4) pyrimidone photoproduction (TT[6-4]) blocking lesion. To measure TLS events, we also employed two known guanine adducts, the N2-acetylaminofluorene (G-AAF) and the benzo(a)pyrene (dG-BaP(−)).

RecB is the major subunit of RecBCD complex and contains the nuclease domain, one of the two helicase domains and the domain for RecA interaction. Acting as a processive nuclease, RecB is able to degrade both strands of a blunt double strand DNA (dsDNA) template, with a preference for the 3′-end. In order to investigate a possible role of the nuclease domain of RecB in HDGR, we used the previously characterized recB[D1080A] nuclease deficient allele (30) that contains a single point mutation in the catalytic core of the nuclease domain that prevents Mg2+ binding. The integration of our lesion-containing vector into the recB[D1080A] strain showed a level of HDGR similar to the parental strain (Figure 2), indicating that the nuclease activity of RecB is dispensable for HDGR. Noteworthy, the bias lagging vs leading in the HDGR level observed in the recB deficient strain is not observed in the nuclease dead allele.

In vivo studies showed that the recB[D1080A] strain is still proficient in DSB repair but entirely relies on the RecFOR complex for this (31,32). Indeed, the D1080A mutation seems to also alter the RecA loading capacity of the RecBCD complex (33), but this is compensated in vivo by the RecFOR complex, the other mediator of RecA loading. We previously showed that a recF recB double mutant strain presents a strong defect in HDGR similar to a recA deficient strain, which suggested independent roles for both RecF and RecB in HDGR. In contrast, as shown in Figure 2, the recF recB[D1080A] double mutant is no more deficient in HDGR than the recF single mutant. This result shows that the contribution of RecBCD to HDGR does not involve its RecA loading activity, nor the processing of DSB that would have arisen from the single lesion.

Since the RecOR complex has been shown to be able to load RecA even in the absence of RecF (10,21,34,35), we tested whether RecOR was able to compensate the RecA loading defect in the recB[D1080A] strain. As shown in Supplementary Figure S1, the defect in HDGR in a recO- strain...
Figure 1. (A) Model of the replication fork encountering a lesion in the leading or lagging strand. (B) Genetic system to monitor sister-strand exchange mechanisms (modified from (4)). The scheme represents the situation in which the lesion (red triangle) is located in the 5′-end of the lacZ gene in the leading strand. The damaged strand containing the marker D, where the lesion is located, and the marker C, placed 100 bp upstream the lesion, contains a +2 frameshift in order to inactivate the lacZ gene. Opposite to the lesion we introduced a +4 loop (marker B) that restores the reading frame of lacZ, and in the same strand we added marker A that contains a stop codon. Therefore, the two strands are lacZ-. Only a mechanism of HDGR by which replication has been initiated on the damaged strand (incorporation of marker C), and where a template switch occurred at the lesion site (leading to incorporation of marker B) will restore a lacZ+ gene (the combination of markers C and B contains neither a stop codon nor a frameshift). Using the same system we can also score for TLS events (combination of marker C and D), as sectored pale blue/white colonies, and for damaged chromatid loss events (combination of marker A + B), as pure white colonies. *For the combination of marker C and D we observed a leaky activity of the β-galactosidase due to a translational frameshift.

is similar to the one in the recF- strain, and the recO recF double mutant doesn’t show any additional defect proving that the two genes are epistatic. More importantly, a recO recB<sup>D1080A</sup> double mutant behaves like a recO single mutant confirming the result obtained in the recF recB<sup>D1080A</sup> strain, and the above conclusion.

The whole RecBCD complex participates to HDGR

Next, we wanted to address the question of whether RecD was dispensable for the HDGR activity of the complex. In vivo RecB needs at least RecC to be functionally active and mutants in either recB or recC gene show a similar phenotype, i.e. recombination deficiency, increased sensitivity to DNA damaging agents and decrease in cell viability (5). On the contrary, a recD null mutant even though deficient for DNA degradation (36) is proficient in recombination and DNA repair because the RecBC complex still possesses the 3′ → 5′ helicase activity of RecB to unwind dsDNA and the ability to load RecA (37,38). Since the nuclease activity of RecB turns out to be dispensable for HDGR and that RecD is the subunit that controls the nuclease activity of the complex, one would expect the deletion of recD not to affect HDGR level (as in a recB<sup>D1080A</sup> strain). Unexpectedly, following the integration of our lesion-containing construct in a recD deficient strain, we observed a decrease in
HDGR similar to a recB deficient strain (Figure 3). However, while in a recB strain HDGR and survival are more affected when the lesion is located on the lagging strand, in a recD strain HDGR and survival decrease more significantly when the lesion is located on the leading strand (Figure 3). This result indicates that the RecD subunit, together with the rest of the complex, is required for HDGR; and that the helicase activity of RecB is dispensable since it is functional in a recD deficient strain and yet, we observe a decrease in the level of HDGR.

The RecD subunit not only controls the nuclease activity of the complex, but it also harbors its own 5′→3′ DNA helicase activity. The decrease in HDGR level observed in the recD deficient strain could be due to the absence of this helicase activity. Therefore, to assess whether the RecD 5′→3′ helicase activity is needed for HDGR, we constructed a helicase dead recD^K177Q mutant where the Lys177Gln substitution in the Walker A motif of the ATPase domain of RecD is known to inactivate the helicase activity (17). Following the insertion of the TT6-4 lesion construct in the recD^K177Q strain, we did not observe any decrease in HDGR in contrast to the reduced HDGR levels measured in the recD deficient strain (Figure 3). This shows that the 5′→3′ helicase activity of RecD subunit is also not required for HDGR. Altogether, these results clearly indicate that none of the helicase activities of RecBCD are required, but rather that the entire RecBCD complex participates in the HDGR mechanism.

RecBCD complex is not a mediator of RecA loading at a single strand gap

Our data indicate that the RecBCD complex is involved in the HDGR mechanism, independently of its nuclease or helicase activities, contrarily to its role played in DSB repair. As previously mentioned RecBCD is, together with RecFOR, a mediator of RecA loading onto ssDNA. While the mediator activity of RecBCD is classically associated with its nuclease and helicase activities, we raised the question whether RecBCD could act as a mediator of RecA during SSG repair, without involving its helicase and nuclease activities. To address this question, we used a specific allele of RecA, the recA730 (E38K) allele, that is able to load itself onto ssDNA without the help of its mediators (39). Previous studies demonstrated in vivo and in vitro that this allele partially complements the phenotype associated with a recF/OR deficient strain (21,40). We modified our plasmid expressing the lambda excisionase/integrase under an inducible promoter (22) by adding either the recA730 allele (pLL59) or the wild-type copy of the recA gene (pLL58) in order to express these alleles in the recipient strains. After ensuring that both plasmids were able to complement a recA deficient strain (Supplementary Figure S2), we transformed those plasmids in a recF deficient strain and monitored HDGR levels. As expected, despite the absence of the RecA mediator (RecF) the level of HDGR is significantly increased (by ∼2 folds) upon expression of the recA730 allele, while no increase is observed upon expression of the wild-type recA gene (Figure 4). The recA730 allele does not fully complement the recF defect, as previously shown (21,40) and as expected since it also fails to fully comple-
Damaged chromatid loss lesions: the guanine adducts. To monitor the effect on TLS at two other significant decrease in the bypass mediated by all three TLS polymerases (Figure 5). To ensure that this effect was not due to the catalytic activities of the RecBCD complex, we also measured TLS in the nuclelease and helicase deficient mutants, recB<sup>D1080A</sup> and recD<sup>K177Q</sup>; we didn’t observe any decrease in the TLS level in these mutants (Figure 5). However, both recB<sup>D1080A</sup> and recD<sup>K177Q</sup> strains are still proficient in DSB repair. To exclude the potential involvement of the formation and repair of a DSB that would be involved in the TLS pathway, we measured TLS in a recF recB<sup>D1080A</sup> and in a recO recB<sup>D1080A</sup> strains that are known to be impaired for DSB repair (31). We didn’t observe any diminution in the level of TLS in these strains when compared to the correspondent single mutant recF and recO (Supplementary Figure S3). It appears therefore that in addition to its role in HDGR, RecBCD is also required for an efficient TLS pathway independently of its catalytic activities and of its capacity to repair DSB.

DISCUSSION

The present work aims at elucidating the role of RecBCD in DNA damage tolerance. RecBCD is one of the most fascinating and studied multienzymatic complexes in bacteria. It is the major recombinational pathway in E. coli responsible for the repair of DSB, conjugational recombination, but also for the degradation of foreign linear DNA, and recently RecBCD was shown to participate in completion of DNA replication (45, 46). We unravel here that, in addition to these many functions, RecBCD also plays a role in SSG repair. Combining our original genetic system to monitor specifically HDGR events with different genetic backgrounds, we show that RecBCD plays a non-catalytic role in HDGR pathway. We also demonstrate that the RecBCD complex is necessary for efficient TLS bypass. Therefore, on the basis of our results, we propose that RecBCD plays a structural role, most likely by preserving the stability of the stalled replication fork to promote an efficient bypass of the lesion, either by TLS or HDGR pathway.

All previous known functions of RecBCD require its nuclease and helicase activities. However, by using specific alleles of RecB (recB<sup>D1080A</sup>) and RecD (recD<sup>K177Q</sup>), deficient respectively for the nuclease and helicase activities, we clearly demonstrate that they are dispensable for HDGR and TLS mechanisms. Our <i>in vivo</i> data that show that gap-repair does not require RecBCD nuclease nor helicase activities is in good agreement with previous <i>in vitro</i> data showing that RecBCD cannot unwind a ssDNA gap, but requires a blunt or nearly blunt double stranded end, and that its nuclease activity is very weak on a gapped substrate (47).

Until now, RecBCD had never been associated with SSG repair unless the ssDNA gap was converted into a DSB (48), its preferred substrate. In our context, it is very unlikely to mediate the loading of RecA on the single strand gap.

The RecBCD complex is also involved in the TLS pathway

Since none of the known catalytic activities of RecBCD seems to be required for its role in HDGR, we hypothesized that RecBCD could play a structural role, possibly by stabilizing or helping in the stabilization of the stalled replication fork. If such stabilization is necessary for an efficient bypass of the lesion, we reasoned that it would be required not only for the HDGR mechanism, but also for the TLS pathway. Since TLS events at the TT(6-4) lesion are very rare events (<0.5%) (Figure 5 and (22)), it is difficult to measure a significant decrease in the recB deficient strain (Figure 5). For this reason, we monitored the effect on TLS at two other lesions: the guanine adducts N-2-acetylaminofluorene (G-AAF) and benzo(a)pyrene (dG-BaP(−)) that show a higher basal level of TLS in the parental strain (see Figure 5 and (41)). When the G-AAF lesion is introduced in the NarI sequence, a potent mutation hotspot, TLS can be mediated either by Pol V (TLS0, non-mutagenic) or by Pol II (TLS2, frameshift -2) (42). The dG-BaP(−) lesion is bypassed by Pol IV (TLS0, non-mutagenic) (43, 44). We used our previously described integration assay that allows to specifically monitor TLS events (22, 41): in a recB deficient strain, we observed a substantial decrease in the bypass mediated by all three TLS polymerases (Figure 5). To ensure that this effect was not due to the catalytic activities of the RecBCD complex, we also measured TLS in the nuclease and helicase dead mutants, recB<sup>D1080A</sup> and recD<sup>K177Q</sup>; we didn’t observe any decrease in the TLS level in these mutants (Figure 5). However, both recB<sup>D1080A</sup> and recD<sup>K177Q</sup> strains are still proficient in DSB repair. To exclude the potential involvement of the formation and repair of a DSB that would be involved in the TLS pathway, we measured TLS in a recF recB<sup>D1080A</sup> and in a recO recB<sup>D1080A</sup> strains that are known to be impaired for DSB repair (31). We didn’t observe any diminution in the level of TLS in these strains when compared to the correspondent single mutant recF and recO (Supplementary Figure S3). It appears therefore that in addition to its role in HDGR, RecBCD is also required for an efficient TLS pathway independently of its catalytic activities and of its capacity to repair DSB.
Figure 4. Partitioning of DDT pathways in strains expressing the recA730 allele. The graph represents the partition of DDT pathways in the presence of the UV lesion TT(6-4) in strains expressing the recA730 allele or the wild-type copy of RecA (indicated in red). In those strains the sulA gene has been also inactivated to avoid cell division blockage because of the constitutively SOS activation due to the recA730 allele. The plasmid pLL59 contains the recA730 allele, while the plasmid pLL58 contains the wild-type copy of recA gene. The lesion has been inserted in either the leading (lead) or the lagging (lag) strands of E. coli chromosome. Tolerance events (Y axis) represent the percentage of cells able to survive in presence of the integrated lesion compared to the lesion-free control. rec+ corresponds to our parental strain, recombination proficient. The data for rec+, recF− and recB− strains have been previously published (4). The data represent the average and standard deviation of at least three independent experiments. t-test was performed to compare values from the double mutants (recA recF or recA recB) to their correspondent single mutant strain (recF or recB). For HDGR: *P < 0.05; **P < 0.005. For damaged chromatid loss: •P < 0.05; ••P < 0.005.

Figure 5. RecBCD complex is involved in TLS pathway. The graph represents the percentage of TLS events in the presence of three different replication blocking lesions (TT6-4, G-AAF, dG-BaP(−)) in the recB−, recB1080A and recD1770 strains (indicated in red) in comparison with a rec+ strain. The data for rec+ strain have been previously published (41,49). The data represent the average and standard deviation of at least three independent experiments in which the lesion has been inserted either in the leading or the lagging strand. The data from leading and lagging strands have been pooled together because no significant difference was observed between the two orientations. t-test was performed to compare TLS values from the recB− strain to the rec+ strain. *P < 0.05; **P < 0.005; ***P < 0.0005.
that the SSG generated at the lesion site is converted into a DSB. Indeed, if this were the case, (i) RecBCD would unwind and resect an extended region of DNA which would require both its nuclease and helicase activities when we actually show that these activities are not required for SSG repair; (ii) such resection would lead to the loss of our genetic markers, while we show that the genetic markers remain stable in the presence of functional RecBCD (4). Further evidence indicating the absence of DSB at the DNA lesion site came from the analysis of the recD deficient strain. This strain has been shown to be still proficient in DNA recombination and DSB repair (36), however when we monitor the level of HDGR in this strain, we observe a decrease similar to the one observed in the recB- strain. These data point towards a different role of RecBCD in DSB and SSG repair: while RecBC are sufficient for DSB repair (with the help of the RecFOR pathway (20), all components of the RecBCD complex are necessary for SSG repair. The recB<sup>D1080A</sup> mutant, whose nuclease is inactivated, conserves its helicase activities and is therefore still proficient for DSB repair provided that the RecFOR complex is present to load RecA. In the absence of RecFOR however, recB<sup>D1080A</sup> becomes deficient in DSB repair. By combining this allele with the recF or recO gene deletion, we observed no effect neither on HDGR nor on TLS compared to the recF or recO single mutant. This again rules out the possibility of RecBCD acting through the repair of a DSB.

After excluding a possible role of the helicase and nuclease domains of RecBCD, we hypothesized that the functional role of RecBCD in HDGR pathway could be to load RecA onto the single strand gap, together with (or in support to) the RecFOR complex, the other known mediator. This could explain the strong phenotype (i.e. similar to a recA deficient strain) we observed in the absence of both RecF and RecB (4). However, when using the recA<sup>T730</sup> allele, that can load itself onto ssDNA without the help of its mediators, we could not complement the deficiency in HDGR in the recB- strain, while recA<sup>T730</sup> allele could partially complement the defect in a recF- strain. This confirms that (i) the decrease in HDGR observed in a recF- strain is indeed due to a defect in RecA loading and (ii) RecBCD is not involved in mediating the loading of RecA to a ssDNA gap. This observation is also corroborated by the analysis of the recB<sup>D1080A</sup> strain. During DSB repair, the mutation in the nuclease domain has been shown to affect the RecA loading activity and the RecB<sup>D1080A</sup>CD complex was then dependent on the mediator activity of RecFOR complex (31,33). In our lesion tolerance assay however, the double mutants recF- recB<sup>D1080A</sup> and recO- recB<sup>D1080A</sup> show a level of HDGR similar to the single recF- and recO- mutants indicating that RecBCD is not an alternative mediator of RecA in SSG repair.

Since the nuclease and helicase activities of RecBCD do not participate in HDGR, and no RecA loading activity was evinced, we surmise that RecBCD functions as a structural element in the HDGR pathway. One possible structural role could be the stabilization of the stalled replication fork. It is important to preserve the integrity of a stalled replication fork to avoid fork collapse, which in turn can lead to DSB formation that can be lethal for the cell. If such stabilization of the replication fork would occur, we reasoned that it would favor not only HDGR, but would also affect TLS. In *E. coli* under non-stressed conditions, TLS events represent a minor pathway compared to the HDGR pathway (22,49). Since the basal level of TLS at the TT(6−4) lesion is very low (~0.5%), it is difficult to observe a clear decrease in TLS following the inactivation of the recB gene (Figure 5). The guanine adducts G-AAF and dG-BaP(−) are more frequently bypassed by TLS polymerases (Pol II/PoL V and PoL IV, respectively) and inactivation of the recB gene in the presence of one of these two lesions results in a substantial decrease of TLS mediated by all three TLS polymerases. This result indicates that RecBCD complex plays a role not only in the HDGR pathway but also in the TLS pathway. The effect on the TLS pathway is not dependent on the catalytic activities of RecBCD neither on the repair of a DSB since we do not observe a decrease of TLS in the nuclease and helicase dead mutants nor in the DSB-repair deficient strains (recF- recB<sup>D1080A</sup> and recO- recB<sup>D1080A</sup>). Altogether these data support the hypothesis that RecBCD plays a structural role in SSG repair, allowing an efficient filling of the gap by HDGR or by TLS. This structural function seems to be more important for TLS, since the absence of RecBCD can lead to a decrease of up to ~80% in TLS events (for dG-BaP), whereas it leads to a decrease of only ~20% in HDGR events. It may be that the way the RecBCD complex participates to DDT is different for TLS and HDGR. Indeed, we observed a slight but reproducible difference of HDGR events between the leading and lagging strand for recB and recD mutants. The defect in HDGR is stronger when the lesion is located on the lagging strand for the recB strain, whereas it is stronger on the leading strand for the recD strain. However, no significant strand bias was observed for TLS in the recB strain. This leading/lagging strand difference for the recB and recD mutants could be explained by the opposite polarity of the helicases harbored by these two subunits. RecB possesses a 3′→5′ helicase whereas RecD possesses a 5′→3′ helicase. Since the inactivation of the helicase activity of RecD (recD<sup>D1770</sup>) strain did not affect the DDT pathways, we rule out the involvement of this catalytic activity. However, it is possible that the protection of the replication fork occurs through the affinity of the helicases for DNA (independently of their activity). Following this hypothesis, the polarity of the RecB helicase would favor binding to the lagging strand whereas RecD would favor protection of the leading strand.

Our finding suggests that the RecBCD complex plays a structural role in SSG repair, most likely preserving the integrity of the stalled replication fork, which is important for both the TLS and HDGR pathways. However, how RecBCD does that still needs to be clarified. We propose that RecBCD binds or somehow protects the 3′-end of dsDNA-ssDNA junction of the stalled replication fork that can be the target of nucleolytic degradation operated by specific nucleases. Degradation of the nascent strand can be detrimental for the activity of the TLS polymerases, since the 3′-end at the lesion site is their cognate substrate. This would explain why inactivation of the recB gene alone has a stronger impact on TLS than on HDGR. If the extent of the degradation is not controlled and becomes too important, this will most likely also affect HDGR. If another
lesion is present on the opposite strand, an extended resection of the non-protected 3′-end would eliminate the dsDNA substrate necessary for homologous recombination at the lesion. The incapacity to repair the gap at either lesion will lead to cell death. This is indeed what we observe in the recB- and recD- strain where the decrease in HDGR is accompanied by a concomitant decrease in survival rather than an increase in damaged chromatin loss. This situation is different than when the RecFOR complex is absent: in that case, HDGR is affected by the delay in RecA loading at the gap, but the 3′-end is not resected and homologous recombination can occur if another lesion is present in the opposite strand.

In the last few years, a similar structural role has been proposed for the breast cancer susceptibility gene 2 (BRCA2) in human cells (50). BRCA2 is a key factor in homologous recombination during DSB repair where it recruits Rad51 (the functional homolog of RecA) to the ssDNA, but it is also involved in other DNA repair processes (reviewed in (51)). Several lines of evidence suggest that BRCA2 protects the stalled replication fork from undesired and harmful nucleolytic degradation, however the underlying molecular mechanisms still need to be completely elucidated (50,52).

In conclusion, we show here that RecBCD plays a non-catalytic role in SSG repair, seemingly by preserving the integrity of the fork and allowing an efficient bypass of the lesion by both TLS and HDGR.

SUPPLEMENTARY DATA
Supplementary Data are available at NAR Online.

ACKNOWLEDGEMENTS
We thank Élodie Chrabaszcz and Jean-Hugues Guervilly for helpful experimental discussions. We thank Pierre-Henri Gaillard and Mauro Modesti for critical reading of the manuscript. We thank Nick Geacintov for the dG-BaP(−) modified oligonucleotides.
