Abstract

The capacity of a *Quercus pubescens* forest to resist recurrent drought was assessed on an *in situ* experimental platform through the measurement of a large set of traits (ecophysiological and metabolic) studied under natural drought (ND) and amplified drought induced by partial rain exclusion (AD). This study was performed during the 3rd and 4th years of AD, which correspond to conditions of moderate AD in 2014 and harsher AD in 2015, respectively. Although water potential (Ψ) and net photosynthesis (P_n) were noticeably reduced under AD in 2015 compared to ND, trees showed similar growth and no oxidative stress. The absence of oxidative damage could be due to a strong accumulation of α -tocopherol, suggesting that this compound is a major component of the *Q. pubescens* antioxidant system. Other antioxidants were rather stable under AD in 2014, but slight changes started to be observed in 2015 (carotenoids and isoprene) due to harsher conditions. Our results indicate that *Q. pubescens* could be able to cope with AD, for at least 4 years, likely due to its antioxidant system. However, growth decrease was observed during the 5th year (2016) of AD, suggesting that this resistance could be threatened over longer periods of recurrent drought.

Keywords: drought, antioxidants, growth, gas exchanges, isoprene emissions

Introduction

Mediterranean forests have high resilience to extreme drought episodes (Lloret *et al.* 2004; Saura-Mas *et al.* 2015). However, predictions based on recent scenarios in the Mediterranean area show a reduction in annual precipitation of up to 30% by the end of this century accompanied by longer periods of summer drought stress (i.e. summer drought intensification) compared to current conditions (Giorgi & Lionello 2008; IPCC 2013; Polade *et al.* 2014). Thus, climate change could consist of recurrent drought periods, extending over years, and the response of Mediterranean forests to such recurrent stress remains largely unknown (Niinemets 2010; Brzostek *et al.* 2014).

Water deficit eventually leads to stomatal closure reducing leaf gas exchange, especially carbon uptake. In this way, the photosynthetic processes could be disturbed and reactive oxygen species (ROS) produced due to limited ability to dissipate light energy and the use of the water-water cycle, hence increasing the oxidative pressure inside leaves (Chaves *et al.* 2009; Ehonen *et al.* 2017). ROS can lead to cell death through damage to proteins, lipids, carbohydrates and/or DNA (Halliwell 2006; Gill & Tuteja 2010).

Plants employ several mechanisms to cope with oxidative stress (Blokhina *et al.* 2003; Jaleel *et al.* 2009). Production of antioxidant-related defence metabolites prevails as a way to tolerate oxidative stress and, *a fortiori*, long-lasting and intense drought periods. A large variety of compounds produced by plants are well known for their antioxidant properties. Carotenoids are an important family of ROS scavengers (Edge *et al.* 1997; Ramel *et al.* 2012), especially those involved in the xanthophyll cycle (violaxanthin, zeaxanthin, antheraxanthin), which protect the photochemical processes by favouring non-photochemical energy dissipation within the antenna of photosystem II (Demmig-Adams & Adams 1996; Reddy *et al.* 2004). The tocochromanols (α -tocopherol and plastochromanol), which are lipid-soluble chloroplastic antioxidants (DellaPenna & Pogson 2006; Kruk *et al.* 2014), and ascorbate and

glutathione, which are water-soluble (Noctor & Foyer 1998), also have strong antioxidant power. Moreover, plants can also produce enzymatic antioxidants such as catalase, peroxidase, superoxide dismutase or thiol reductases (Ahmad *et al.* 2010).

Besides these universal antioxidants, plants also produce other types of antioxidants, such as terpenes and phenolic compounds, whose diversity is non-universal or species-specific. Isoprene, the main volatile terpene emitted by plants, seems to maintain the membrane stability of thylakoids preserving the photosynthetic machinery under oxidative conditions (Affek & Yakir 2002, Velikova *et al.* 2011). Moreover, phenolic compounds, especially phenolic acids, flavonoids and tannins, feature a strong capacity to quench ROS (Close & McArthur 2002). As a result, both terpenes (including isoprene) and phenolic compounds are expected to be increasingly produced in response to abiotic oxidative pressures, which is in accordance with the unified mechanism of action for volatile terpenes (Vickers *et al.* 2009) and the oxidative pressure theory for phenolic compounds (Close *et al.* 2004).

Several studies reviewed in Munné-Bosch (2005) provide evidence that plant protection against oxidative stresses is not due to a single compound, but to the whole bouquet of antioxidants. They also show that compensatory mechanisms can occur between antioxidants as well as between antioxidants and growth. Antioxidant synthesis requires carbon allocation, but this allocation could be limited under intense drought since photosynthetically assimilated carbon is limited (Chaves *et al.* 2003). This trade-off or compensation is, however, not necessarily observed since primary reserves of plant carbohydrates (starch for instance) can be mobilized to support metabolite production (Brilli *et al.* 2007; Chaves *et al.* 2009). Numerous studies have already focused on gas exchange and/or growth and/or antioxidant concentration or emission under several drought treatments, mostly applied under controlled conditions, and more rarely under natural conditions (Llusà & Peñuelas 1998; Jiang & Zhang 2002; Hernández *et al.* 2004). However, there is still a lack of knowledge on how plants resist

in situ amplified recurrent drought (several years), especially in the Mediterranean area where plants often encounter this type of stress.

Quercus pubescens Willd, our vegetal model, is one of the most widespread species in the Northern part of the Mediterranean basin. This species is a thermophilic and xerophilic species, highly resistant to drought conditions. This study aimed to evaluate if *Q. pubescens* forest can resist the recurrent and amplified drought expected with climate change in the Mediterranean region. We addressed the aim by measuring a vast array of ecophysiological (pre-dawn and midday water potential, stomatal conductance to water, net photosynthesis, chlorophyll content, chlorophyll fluorescence and lipid peroxidation as a direct proxy of cell oxidation) and metabolic (non-universal and universal antioxidants) traits. We hypothesized that (i) recurrent amplified drought (AD) could increase the oxidative pressure in leaves, leading to modifications of the antioxidant system, and (ii) carbon assimilation decrease with recurrent AD would involve trade-offs or compensations between antioxidants or between antioxidants and growth.

Materials and Methods

Experimental site

The study was performed at the Oak Observatory at the “Observatoire de Haute Provence (O₃HP)”, located 60 km North of Marseille (5°42'44" E, 43°55'54" N), at an elevation of 650 m above sea level. The O₃HP (955 m²), free from human disturbance for more than 70 years, consists of a homogeneous forest mainly composed of *Q. pubescens*, aged 70 years-old. This forest site features a supra-Mediterranean sub-humid bioclimate with an average annual precipitation of 830 mm, averaged from 1967 to 2000 (Santonja *et al.* 2015). Hence, this is considered a site with a Mediterranean climate, but with the peculiarity that the dry period naturally takes place for just one or two months per year. Using a rainfall exclusion device

mechanically deployed to exclude some rain events (Fig. 1), it was possible to reduce natural annual rain by ~30% over part of the O₃HP canopy, hereafter referred to as “the amplified drought plot” (AD). This method allowed us to extend the drought period, in an attempt to mimic the current climatic model projections for the end of this century (Giorgi & Lionello 2008; IPCC 2013; Polade *et al.* 2014). Two plots were present in the site: a plot (300 m²) subjected to amplified drought (AD) and an adjacent plot (232 m²), which received natural precipitation where trees were subjected to natural drought (ND). Amplified drought started in April 2012 and continued each year from then, principally during the growth period, with a 35% exclusion of precipitation in 2012 (from April 29th to October 27th), 33% in 2013 (from July 7th to December 29th), 35.5% in 2014 (from April 8th to December 8th) and 33.9% in 2015 (from April 16th to November 21st). Ombrothermic diagrams - built up using values of precipitation and temperature measured through rain gauges and temperature sensors placed in both plots - indicate that the drought period in the AD plot was extended for 2 months in 2012, 4 months in 2013, and 3 months in 2014 and 2015 compared to the ND plot (Fig. 2). Moreover, in 2014, 1167 mm of cumulative precipitation was recorded under ND and 753 mm under AD whereas, in 2015, precipitation dropped to 598 mm in the ND plot and 395 mm in the AD plot (Fig. 3) indicating that, in our experiment, 2014 was a wet year whereas 2015 was considered a dry year.

Six measurement campaigns were performed during this study, three in 2014 and three in 2015, corresponding to the 3rd and 4th year of AD. For each year, one measurement campaign was performed in spring (May 9th-18th 2014 and May 15th-29th 2015), summer (July 11th-19th 2014 and July 18th-28th 2015) and autumn (September 30th-October 6th 2014 and September 18th-30th 2015). The sampling was performed at the branch scale at the top of the canopy on the same five trees per plot throughout the 6 measurement periods (position of the trees can be found in Fig. 1) and two additional trees per plot were included for antioxidant analyses

(tocochromanols, chlorophylls and carotenoids). Trees were chosen randomly in the heart of each plot (to avoid the buffer zone of 2 m at the verges of the AD plot) while having canopies accessible from the footbridge.

Ecophysiological traits

CO₂ and H₂O exchange

Two identical dynamic branch enclosures were used for sampling CO₂ and H₂O exchange as well as isoprene emission (see below). The enclosures are fully described in Genard-Zielinski *et al.* (2015) and only slight modifications were made as described in Saunier *et al.* (2017).

Branches used for gas exchange sampling were located at the top of the canopy and exposed to the sun. Each branch was enclosed for 2 days in a ≈ 30 L PTFE (polytetrafluoroethylene) frame closed with a 50 μ m thick PTFE film. Branch enclosures were installed on the day before the first measurement and were immediately flushed with a continuous flow of purified air at 9 L.min⁻¹ (allowing complete air renewal every 3.33 min) using a PTFE pump (N840.1.2FT.18, KNF, Germany). A PTFE fan was used to ensure a rapid mixing of the chamber air and a slight positive pressure within the enclosure enabled it to be held away from the leaves to avoid biomass damage. Exchange of CO₂ and H₂O of the enclosed branches were continuously measured (every minute) using infrared gas analyzers (IRGA 840A®, LI-COR, USA) at 0.2 L.min⁻¹. Net photosynthesis (P_n , μ molCO₂ m⁻² s⁻¹), stomatal conductance to water (G_w , mmolH₂O m⁻² s⁻¹) and transpiration rate (E , mmolH₂O m⁻² s⁻¹) were calculated using equations described by Von Caemmerer and Farquhar (1981) as presented in Genard-Zielinski *et al.* (2015). Transpiration rate data are not presented in this work, but were used to calculate the water use efficiency (WUE , mmolCO₂.molH₂O⁻¹) as P_n/E . All gas exchange data were averaged between 12:00 and 15:00 (local time).

Relative humidity (RH) and temperature (T) were measured using an RHT probe (HMP60, Vaisala, Finland) placed inside the chamber and photosynthetically active radiation (PAR) was measured using a quantum sensor (PAR-SA 190®, LI-COR, USA) placed outside the chamber. Measurements with the RHT probe and the PAR sensor were recorded every minute using a data acquisition system (data logger, Li-1400– 04®, LI-COR, USA). Once CO₂ and H₂O exchange had been measured, leaves from enclosed branches were collected in order to calculate the surface area of each leaf with a leaf area meter (AM350, ADC Bioscientific Ltd., UK) and to report gas exchange of the whole branch leaf surface. The foliage used for the water potential and biochemical analyses was taken from branches adjacent to those enclosed and used for the gas exchange measurements.

Stem water potential

Stem water potential at predawn (Ψ_{pd}) and midday (Ψ_m) were measured from detached stems during each field campaign (except Ψ_{pd} in spring 2014 and Ψ_m in autumn 2014) with a Scholander pressure chamber (PMS instrument Co., USA, range 0 - 7Mpa). Two measurements of Ψ were performed on each tree if the difference between both values did not exceed 0.3 MPa. Otherwise, a third measurement was performed.

Chlorophyll fluorescence

Chlorophyll fluorescence of photosystem II was measured through the maximum quantum efficiency of PS II (F_v/F_m , the ratio of variable to maximum fluorescence). Measurements were performed on the adaxial side of the leaves, with the leaves dark-adapted for at least 30 min, using a portable fluorimeter (FMS2, Hansatech, UK).

Chlorophyll pigment

For all biochemical analyses (i.e. including the metabolic traits studied, see below), leaf samples were frozen in liquid nitrogen and stored at -80°C before measurements. Chlorophyll pigments were extracted from leaves in methanol, quantified by HPLC using authentic standards of chlorophyll *a* and *b* (Sigma-Aldrich, USA) and expressed in $\text{mg}\cdot\text{g}_{\text{DM}}^{-1}$, as described by Havaux *et al.* (2007). The ratio between chlorophyll *a* and *b* (*Chl a/Chl b*) was also calculated as an indicator of PSII antenna size and PS stoichiometry.

Estimation of leaf oxidation through lipid peroxidation imaging

Lipid peroxidation was visualized in detached leaves by autoluminescence imaging to assess leaf oxidation due to water stress (Havaux *et al.* 2006). As detailed in Birtic *et al.* (2011), this technique is based on the measurement of the weak luminescence associated with the slow decomposition of lipid peroxides using a very sensitive photon-imaging system. The intensity of the luminescence signal is proportional to the amount of lipid peroxides present in leaves. In order to validate the applicability of this method on Downy oak, detached leaves were exposed to a photooxidative stress treatment by combining high PAR ($1500 \mu\text{mol m}^{-2} \text{s}^{-1}$) and low temperature (14 °C). Spontaneous photon emission from detached Downy oak leaves was measured after 3 h of dark adaptation using a liquid N₂ cooled charge-coupled device (CCD) camera. Acquisition time was 20 min and pixel binning was 2 x 2. The luminescence signals were analyzed and quantified with Image J software.

Growth assessment

Growth was estimated in ND and AD plots through 3 parameters: i) litter production ($\text{g}\cdot\text{m}^{-2}$) as a direct proxy of leaf biomass production, ii) increase of tree trunk diameter at breast height (DBH, $\text{cm}\cdot\text{yr}^{-1}$) and iii) leaf mass per unit of leaf area (LMA, $\text{g}\cdot\text{m}^{-2}$) indicator of foliage thickness (Vile *et al.* 2005). Litter production was measured within 8 litter traps (0.24 m^2)

placed on the soil of both plots in 2014 and 2015. Litter traps allowed the collection of senescent leaves during leaf abscission from October to April and thus estimation of the leaf biomass production in each plot. The DBH increase was measured as the difference between DBH in 2016 (5th year of AD) and DBH in 2015 (4th year of AD), DBH being always measured at the end of the vegetative period (in December). Note that DBH is the only parameter monitored in 2016. These measurements were performed on all trees of each plot (n=146 in ND and n=52 in AD) with a meter (tape measure). Finally, the LMA of enclosed leaves was measured as the ratio between the dry leaf biomass and weight, expressed in g.m⁻². LMA is only presented for autumn 2014 and 2015 for trees followed for gas exchange. We assumed that it was a representative measurement for the whole year as *Q. pubescens* is a winter-deciduous species.

Metabolic traits

For all metabolic traits studied, leaf samples were collected and immediately frozen in liquid nitrogen and stored at -80°C in a laboratory freezer before extractions.

Tocochromanols

The α -tocopherol and plastochromanol concentrations (ng.mg_{DM}⁻¹) were extracted using the method described by Ksas *et al.* (2015), which was adapted from Kruk and Karpinski (2006). α -tocopherol standards were obtained from (Sigma Aldrich, USA) and the plastochromanol standard was a kind gift from Dr. J. Kruk (Jagiellonian University, Krakow, Poland).

Carotenoid pigments

Antioxidant carotenoid pigments from the xanthophyll cycle (violaxanthin+antheraxanthin+zeaxanthin), as well as neoxanthin, lutein and β -carotene were extracted and analyzed using

the same method used for chlorophylls (see above, Havaux *et al.* 2007). Their concentrations ($\text{ng.mg}_{\text{DM}}^{-1}$) were calculated from calibration curves performed using pigment standards (Extrasynthèse, France).

Isoprene

A commercial PTR-ToF-MS 8000 instrument (Ionicon Analytik GmbH, Austria) was used for online measurements of isoprene emissions (Tholl *et al.* 2006; Jordan *et al.* 2009) in the enclosure chambers (measurements performed in parallel to gas exchange measurements). A detailed description of the instrument and sampling set up have been previously published (Saunier *et al.* 2017). Isoprene mixing ratios were calculated based on the signal intensity at m/z 41.038 and 69.069 using a proton transfer rate constant of $1.95 \cdot 10^{-9} \text{ cm}^3 \text{ s}^{-1}$ as reported by Cappellin *et al.* (2012). Isoprene emissions rates (*ERiso*) between 12:00 and 15:00 (local time), when emissions were the strongest, were calculated by considering the concentrations at the inlet and outlet of the PTFE chamber using the following equation:

$$ER_{iso} = \frac{Q_0 (C_{out} - C_{in})}{B}$$

where *ERiso* is expressed in $\mu\text{gC g}_{\text{DM}}^{-1} \text{ h}^{-1}$, Q_0 is the flow rate of the air introduced into the chamber (L h^{-1}), C_{out} and C_{in} are the isoprene concentrations in the outflowing and inflowing air respectively ($\mu\text{gC L}^{-1}$) and B is the total dry biomass matter (g_{DM}). *ERiso* are not available for autumn 2014 due to a technical problem. Investment of carbon sequestration into isoprene (C_{iso}) was calculated with the following formula:

$$C_{iso} = \frac{ER_{iso}}{P_n}$$

where *ERiso* and P_n used in this equation were expressed in $\mu\text{gC m}^{-2} \text{ h}^{-1}$.

Total phenolic compound index

Total phenolic compounds index, were extracted using 0.25 g_{DM} of lyophilized ground leaves in 20 mL of methanol:water solvent (70:30). The mixture was shaken constantly for 1 h at ambient temperature and the extract was then filtered through a membrane with a 0.22 µm pore size. The total amount of water-soluble phenolic compounds was determined based on the Folin-Ciocalteu method used by Santonja *et al.* (2015). The quantitative values were expressed in mg equivalents of gallic acid per g of leaf dry mass.

Starch

Starch was extracted from 0.1 g_{DM} of lyophilized ground leaves in 100 µL of ethanol/water solvent (80:20). After addition of 3 mL of amylase, each sample was incubated in boiling water for 6 min and 100 µL of amyloglucosidase was then added. The samples were mixed and incubated for 30 min at 50 °C and then transferred into graduated 25 mL vials. Volumes were adjusted up to 25 mL with distilled water. An aliquot was centrifuged at 3000 rpm for 10 min. Then, 50 µL of each sample was mixed with 2 mL of distilled water, 100 µL of buffer solution and 100 µL of NADP⁺ solution. After 3 min, the extract was measured at 340 nm on a Biomate 3 spectrophotometer (ThermoFisher, USA). A calibration curve was made with a D-glucose solution provided with the analytical kit (Megazyme, USA).

Statistical analyses

Statistical analyses were performed with STATGRAPHICS® centurion XV (Statpoint Technologies, USA) and R (3.3.2). To evaluate differences between the factors "drought treatments" and "seasons" on every plant trait, we separated the data set in 2014 and 2015, and performed a two-way repeated measures ANOVA followed by Tukey *post hoc* tests after having checked the normality and homoscedasticity of the data set. Since significant interactions between drought and seasonality occurred, we performed a one-way repeated

ANOVA followed by Tukey *post hoc* tests to evaluate the effect of season on ND and AD separately, and Student tests to evaluate differences between ND and AD during each season. Student's tests were also performed to test for differences between both years. Student tests allowed the analysis of differences in growth between AD and ND. In order to check for the occurrence of compensatory mechanisms (increasing the production or emission of some antioxidants as others decrease), Spearman correlations were performed between antioxidants. Spearman correlations were also used to assess the relationship between antioxidants and physiological parameters (P_n and Ψ_{pd}). Correlations were always carried out for each season with years and treatments pooled together.

Principal component analyses (PCA) were performed on antioxidant data for each season, (previously centered and standardized) in order to highlight whether some compounds were produced more under AD in 2014 and 2015 (ade4 package in R) followed by two-way PERMANOVA to check for significance of the results (vegan package in R).

Results

Water stress level indicators

Amplified drought had a strong effect on Ψ_{pd} with decreases of 22 and 29% in summer and autumn of 2014, respectively, and 12 and 43% in summer and autumn of 2015, respectively (Table 1). Ψ_{pd} in 2014 was higher than in 2015: in summer 2014, Ψ_{pd} dropped to -0.70 and -0.90 MPa in ND and AD, respectively, whereas in summer 2015, Ψ_{pd} reached -2.41 and -2.74 MPa in ND and AD, respectively. Differences in Ψ between AD and ND only occurred in terms of Ψ_{pd} (i.e. no differences in terms of Ψ_m), except for a drop (-21%) in Ψ_m under AD in autumn 2015. G_w was clearly reduced by AD, which was especially clear in 2015 (~ -95% in summer and autumn) compared to 2014 (from -39 to -56%). The pattern observed for P_n was the same as for G_w with a stronger limitation under AD in 2015 (-61% and -85% in summer

and autumn) compared to 2014 (~ -33% over the year). In spring, *Pn* did not show any modification under AD irrespective of the year. WUE only increased under AD in spring 2014 and summer 2015.

Total Chl and *Chl a/Chl b* ratio only showed a significant drop under AD in 2015, with the effect especially noticeable in autumn with a decrease of 15%. Increase of the ratio was due to an increase of *Chl a* in spring whereas it was due to a decrease in *Chl b* in autumn. No change was observed in terms of *Fv/Fm* when trees grew under AD, either in 2014 or 2015. Likewise, starch content did not change with drought treatment, irrespective of the year.

Autoluminescence imaging was used to detect lipid peroxidation in *Q. pubescens* leaves. Under photooxidative stress conditions, a high leaf autoluminescence was found for all leaves. This indicates, as expected, strong lipid oxidation, and confirms the applicability of the method for this species (Fig. 4, HL). In both 2014 and 2015, leaf autoluminescence was very low throughout the year and did not increase with AD.

Growth

Neither leaf biomass production, nor LMA varied between ND and AD in any year tested (Table 2). However, trunk growth, estimated by the DBH increase between 2015 and 2016, was reduced by 43% under AD compared to ND.

Antioxidants

Sensitivity to amplified drought and seasonal course

Leaf α -tocopherol concentration was not sensitive to AD, irrespective of the season or the year (Fig. 5a and 5b). However, α -tocopherol was sensitive to seasonal changes with a marked accumulation of α -tocopherol through the seasonal cycle, with minimal, intermediate and maximal concentrations in spring, summer and autumn, respectively, especially in 2015.

Likewise, plastochromanol concentrations accumulated from spring to autumn in both 2014 and 2015, and were not affected by AD in 2015 (Fig. 5c and 5d). However, plastochromanol concentrations increased under AD in 2014, whereas increases were not observed for any of the other antioxidants analyzed.

The concentration of lutein, the major carotenoid in leaves, decreased significantly both under severe AD conditions in 2015 (-24% and -18% in summer and autumn, respectively; Fig. 6a and 6b) and throughout the year (spring > summer > autumn) in 2014 and 2015, contrasting with the trend for tocochromanols. β -carotene content followed the same pattern as lutein in 2015 with decreases under AD (-14% and -22% in summer and autumn, respectively; Fig. 6c and 6d) and a drop in concentration over the year. The seasonal pattern of β -carotene in 2014 consisted of a maximal content in summer. Neoxanthin concentration did not vary under AD in 2014, but was also markedly reduced under AD in summer 2015 (Fig. 6e and 6f). Neoxanthin content showed the same seasonal changes as β -carotene in both years.

Content of the xanthophyll cycle carotenoids (violaxanthin, antheraxanthin and zeaxanthin) was not affected by precipitation restrictions either in 2014 or 2015, except for in autumn 2015 when there was a decrease of 20%. These antioxidants followed a seasonal cycle with a decrease throughout the year during both years, as described for the other carotenoid antioxidants in 2015. Because their response to drought treatment and seasonality was the same and they were issued from the same biochemical cycle, the whole concentration of violaxanthin+antheraxanthin+zeaxanthin is shown throughout the paper.

Isoprene was down-regulated antioxidant since 2014 under AD (Fig. 7) with a decrease in emissions of 50% and 35% in spring and summer 2014, respectively. In 2015, when drought was especially intense, isoprene emissions remained low under AD (especially in autumn with -61% compared to trees in the ND plot). We also noted that trees growing in the ND plot showed similar isoprene emission rates during the summers of both years (115.2 ± 17.9 and

124.3±17.9 $\mu\text{g C g}_{\text{DM}}^{-1} \text{ h}^{-1}$ in 2015 and 2014, respectively) while larger emissions were observed in spring 2015 relative to 2014 (42.5±12.0 and 20.3±3.8 $\mu\text{gC g}_{\text{DM}}^{-1} \text{ h}^{-1}$). The same pattern was observed in the AD plot with higher emissions in spring 2015 compared to 2014 (40.3±9.2 and 10.2±2.3 $\mu\text{gC g}_{\text{DM}}^{-1} \text{ h}^{-1}$). With regard to seasonality, we observed the same pattern during both years with the strongest emission rates recorded in summer compared to the other seasons. Carbon assimilated through *Pn* was clearly more invested into isoprene during the summer compared to the other seasons. This investment (similar between AD and ND) was especially clear in summer 2015 when ~15% of the fixed CO₂ was re-emitted as isoprene compared to about 3% in 2014 (Fig S1, in supplementary file).

Phenolic compounds index was not sensitive to AD either in 2014 or 2015 (Fig. 8). Moreover, these compounds did not exhibit a seasonal course, irrespective of the year, with similar concentrations during both years.

Main antioxidants vary according to the season and the year

Antioxidant concentrations mostly remained similar under both drought treatments (Fig. 9a, b, c, PCA, followed by two ways PERMANOVA), except in summer when AD had a marginal effect. By contrast, antioxidant concentrations were strongly dependent on the year and season: *i*) in spring, β -carotene and, to a lesser extent, isoprene and α -tocopherol were produced in greater amounts in 2015 compared to 2014; *ii*) in summer, α -tocopherol, plastochromanol and carotenoids belonging to the xanthophyll cycle were produced in greater amounts in 2015. Isoprene and phenolic compounds did not have a high impact on the data repartition for the summer season; *iii*) in autumn, the xanthophyll cycle carotenoids, α -tocopherol and isoprene were produced in greater amounts in 2015 than 2014. Similar to the data for the summer, data repartition in autumn was not highly affected by phenolic compounds.

Compensatory mechanisms

Spearman's correlations between antioxidants and physiological parameters (P_n and Ψ_{pd}) showed that, in spring, xanthophyll cycle antioxidants were positively correlated with P_n (Table 3 and Tables S1 a and b in supplementary files). In summer, the xanthophyll cycle antioxidants, as well as α -tocopherol, were strongly and positively correlated with the drop in water availability (indicated by Ψ_{pd}), involving a decrease in carbon assimilation. Moreover, the drop in water availability was also associated with a decrease in carotenoids (β -carotene and neoxanthin), as indicated by their negative correlation. In autumn, just like in summer, α -tocopherol and xanthophyll cycle antioxidants were positively correlated with the decrease of Ψ_{pd} , which was negatively correlated with neoxanthin.

In each season, the three carotenoids, lutein, β -carotene and neoxanthin, were positively correlated: *i*) in spring, only positive correlations were observed between antioxidants, with isoprene positively correlated with neoxanthin and β -carotene positively correlated with α -tocopherol; *ii*) in summer, α -tocopherol was negatively correlated with carotenoids (lutein, β -carotene and neoxanthin) and positively correlated with the xanthophyll cycle. Plastochromanol was also positively correlated with the xanthophyll cycle; *iii*) in autumn, α -tocopherol was negatively correlated with neoxanthin and the latter was also negatively correlated with isoprene emissions and xanthophyll cycle pigments. Moreover, isoprene, xanthophyll cycle antioxidants and α -tocopherol were positively correlated with each other. Negative correlations are probably indicators of trade-offs or compensations between antioxidants, whereas positive correlations could reflect synergistic actions of antioxidants.

Discussion

Amplified drought affects gas exchange by *Q. pubescens* leaves.

Under mild water deficit in 2014 (Ψ_{pd} close to - 1.0 MPa in summer AD), *Q. pubescens* exhibited partial stomatal closure (50% lower under AD than ND in summer). Although this response resulted in a 40 % decrease of P_n , it had the advantage of avoiding Ψ_m drop under AD (conservative strategy). This response reflects a drought-resistance strategy through drought-avoidance (Martínez-Ferri *et al.* 2000). However, it also suggests that *Q. pubescens* showed some degree of drought tolerance since, despite the substantial P_n decline, P_n values were still rather high ($\sim 9 \mu\text{molCO}_2 \text{ m}^{-2} \text{ s}^{-1}$ in summer) (Damesin and Rambal 1995) during this relatively wet year. It should be noted that *Q. pubescens* exhibits other drought-avoidance traits, including a well-known high stem hydraulic efficiency, which is also partly responsible for leaf water maintenance (Nardini & Pitt 1999; Poyatos *et al.* 2008; Genard-Zielinski *et al.* 2014).

In 2015, when harsher drought conditions occurred (up to $\Psi_{pd} \sim -3$ MPa in summer under AD), *Q. pubescens* closed its stomata under AD during most of the year (except in spring), which implied a marked limitation of P_n . This strategy seemed, however, more efficient in summer than in autumn since stomatal closure under AD in summer prevented Ψ_m from dropping compared to ND (drought-avoidance), while in autumn, stomatal closure implied limited P_n , but could not prevent Ψ_m decline, showing the limits of *Q. pubescens* resistance to drought.

Our study indicates that *Q. pubescens* features high plasticity when faced with water scarcity, with a shift from combined drought-avoidance and -tolerance responses under mild water deficit (2014) to a drought-avoidance strategy under more severe dryness (2015). This shift between drought-resistance strategies with respect to gas exchange seems to be common in Mediterranean species (Chaves *et al.* 2009).

It is important to note that the net photosynthesis decrease observed in 2015 is likely to be due to the harsher climatic conditions of that year, but could also be due to the cumulative effect of recurrent amplified drought as expected with climate change (Brzostek *et al.* 2014). These

results suggest that, besides the drought severity of the year, drought recurrence is also a major factor to take into account when evaluating species resistance to expected climate change.

The antioxidant system preserves *Q. pubescens* leaves from drought-induced oxidative damage

The low levels of lipid peroxidation observed in this study (indicator of *Q. pubescens* resistance to water stress) implies that leaves were able to avoid cellular oxidative damage during drought stress, presumably due to several metabolic adjustments and compensations.

In 2015, AD brought about a decrease in lutein, neoxanthin and β -carotene compared to ND, which is concomitant with the Ψ_{pd} drop. This decrease could be due to the oxidative pressure occurring within leaves resulting in carotenoid oxidation, as demonstrated by Ramel *et al.* (2012). It is possible that this phenomenon was not efficient enough to protect chloroplasts from oxidative damage since a compensatory mechanism between carotenoids and α -tocopherol (negative correlation) was highlighted. This loss of carotenoids, together with an increase in chl a /chl b , could also come from reduction of the PSII antenna in AD-treated leaves, since both lutein and neoxanthin are components of the light-harvesting antenna of the photosystems, with neoxanthin being specific to the PSII antenna (Croce *et al.* 1999). This phenomenon is a typical response of plants to excess light energy (Park II *et al.* 1997; Ballottari *et al.* 2007). However, the maximal quantum efficiency of PSII (F_v/F_m) was not affected by AD, indicating that there was no photoinhibition and that PSII was still functional despite the loss of pigments (Krause & Weis 1991). Thus, the carotenoid changes could actually reflect an acclimation to light and drought in 2015 and their role as antioxidants through oxidation reactions.

A striking observation was that lipid-soluble antioxidants (α -tocopherol, plastochromanol) displayed a very strong accumulation in *Q. pubescens* leaves throughout the year, both in 2014 and 2015. Compared to spring, α -tocopherol and plastochromanol contents were increased in autumn by a factor of around 8. Both tocopherol and plastochromanol are known to be located in the chloroplasts (Kruk *et al.* 2016) and are dependent on light, with an excess of light energy boosting their synthesis (Ksas *et al.* 2015). The strong accumulation of those compounds in *Q. pubescens* leaves in summer and autumn suggests that trees perceived cellular oxidative stress and responded by inducing synthesis of lipid-soluble antioxidative molecules to protect their chloroplast membranes. Thus, lipid-soluble antioxidative molecules, especially α -tocopherol, appeared to play a key role in resilience of the Downy oak forest under recurrent drought.

It was, however, surprising that the accumulation of tocochromanols was similar between ND and AD, although significant perturbations of the photosynthetic apparatus were observed in 2015 under the AD compared to ND. Even though there were no differences between ND and AD, α -tocopherol contents increased with the Ψ_{pd} drop as well as with the decrease of carbon assimilation, confirming that this compound plays an important role against water stress (Munné-Bosch & Alegre 2003; Munné-Bosch *et al.* 2004; Jaleel *et al.* 2008). By contrast, plastochromanol did not show this kind of correlation, suggesting a less pronounced role than for α -tocopherol in the *Q. pubescens* antioxidant response to drought. Moreover, the correlation found between α -tocopherol and the xanthophyll cycle is interesting because those compounds are known to have overlapping antioxidant functions as thylakoid membranes protectors (Havaux & García-Plazaola 2014). The increase of the xanthophyll cycle content concomitantly with the Ψ_{pd} drop confirms this overlap hypothesis. These results suggest that the xanthophyll cycle also plays a key role in the *Q. pubescens* antioxidant system.

A similar study was performed in 2012 (first year of AD) on isoprene emissions from the same trees (Genard-Zielinski *et al.* 2017) and highlighted an increase in this compound, whereas we observed a decrease after the 3rd and 4th years of AD. Decreases in isoprene emissions could be problematic for *Q. pubescens* as this compound is known to act as an antioxidant and maintain the stability of thylakoid membranes under oxidative conditions (Velikova *et al.* 2011). The antioxidant system of *Q. pubescens* could be affected by the isoprene decrease through compensatory mechanisms (Munné-Bosch 2005), but this was apparently not the case since no strong trade-off (indicated by a negative correlation) was detected between isoprene and the major antioxidants (e.g. α -tocopherol, xanthophyll cycle antioxidants). By contrast, several positive correlations with these major antioxidants were detected. These results suggest that isoprene could act as an additional antioxidant favoured only in the earlier steps of drought as highlighted in our studies (1st, 3rd and 4th years). The release of assimilated carbon in isoprene could confirm this hypothesis, as this parameter was higher during the 1st year under AD (Genard-Zielinski *et al.* 2017) whereas it was the same between treatments after the 3rd and 4th years.

Although phenolic compounds are well known to have a role in photoprotection (Dixon & Paiva 1995) and are associated with drought resistance (Hernández *et al.* 2004; Akula & Ravishankar 2011), they did not respond to drought conditions in our study. Moreover, they did not show compensatory mechanisms or a synergic action with other antioxidants. There is a large variety of phenolic compounds in plants (e.g. flavonols, flavanols, anthocyanins) with many different roles and effects on oxidative stress (Close & McArthur 2002). For example, it has been demonstrated that the monomeric flavan-3-ols (e.g. catechins), a particular group of flavonoids, had an *in vitro* antioxidant activity five times higher than tocopherol or ascorbic acid (Blokina *et al.* 2003). Thus, it is possible that specific groups or individual phenolic

compounds rather than the total phenolic content respond to AD (Bernal *et al.* 2015), which could not be seen with our global analysis.

Growth of *Q. pubescens* could be affected by amplified drought in the long term

Trees seemed to invest similarly into growth under ND and AD until 2015, at least in terms of leaf biomass production. However, the trunk growth estimated by the increase in DBH started to significantly differ between 2015 and 2016 (between the 4th and the 5th year of AD), indicating that a relatively long period of water stress is needed to observe a significant growth decline in this species. Therefore, the effects of AD on oak forest growth could be amplified in the coming years. This result could be due to the limiting conditions in terms of precipitation in 2015 or to the recurrent drought (Smith *et al.* 2009). Moreover, *Q. pubescens* produced the same quantities of leaves under ND and AD irrespective of the year, which supports this hypothesis. Likewise, Limousin *et al.* (2012) showed that growth of *Q. ilex*, another major Mediterranean species, was impacted only after 7 years of precipitation restriction in the field.

As a general conclusion, the present work shows that the predicted decrease in rainfall of 30% by the end of the century associated with climatic change will not strongly affect Downy oak forest ecosystems in the Mediterranean area in the mid-term (after 4 years). Although *Q. pubescens* is a highly drought-resistant species that possesses efficient antioxidant mechanisms (tocopherol, xanthophyll cycle) to cope with oxidative stress, we can anticipate substantial decreases in gas exchange, adjustments of the photosynthetic pigment composition (chlorophylls, carotenoids), impaired growth in the long-term and maybe stronger compensatory mechanisms between antioxidants.

Even though our study highlights the occurrence of a few metabolic and ecophysiological shifts with water stress recurrence and severity, these investigations could be expanded in further studies by integrating other compounds that are indicators of plant protection against water stress (e.g. enzymatic antioxidants, targeted phenolic compounds, sugars), and by considering longer time scales (probably up to 10 years). This would allow the evaluation of whether the observed shifts in this study become more marked over time and/or the more complete extent of Downy oak resilience. Indeed, as indicated by a European study (Kröel-Dulay *et al.* 2015) that has investigated the impact of climate change on ecosystems under natural conditions, long periods (over 7 years) of environmental stress may be necessary to observe a negative impact on a given ecosystem, especially in undisturbed ecosystems.

Acknowledgments

This work was supported by the French National Research Agency (ANR) through the SecPriMe² project (ANR-12-BSV7-0016-01), Europe (FEDER) and ADEME/PACA for PhD funding. We are grateful to FR3098 ECCOREV for the O3HP facilities (<https://o3hp.obs-hp.fr/index.php/fr/>). The authors thank the MASSALYA instrumental platform (Aix Marseille Université, ice.univ-amu.fr) for the analysis and measurements of BVOC used in this publication. We are very grateful to J.-P. Orts (IMBE) and I. Reiter (ECCOREV) for their help at the O3HP platform and S. Tourrette (BVME) for some biochemical analyses. We also thank all members of the DFME team from IMBE and, particularly, S. Greff and S. Dupouyet, for their help during measurements and analyses.

Author contribution

A.S., E.O., M.H. and C.F. designed the research and the experimental design. A.S., B.T.R., E.O., M.H. and C.F. conducted the research. A.S., E.O., M.H., B.K., B.T.R., J.P.M. and C.L.

collected and analyzed the data. A.S., E.O., H.W., B.T.R., M.H., J.P.M., A.B.M., T.G. and C.F. wrote the manuscript

Table 1 Pre-dawn water potential (Ψ_{pd} , MPa), midday water potential (Ψ_m , MPa), net photosynthesis (Pn , $\mu\text{molCO}_2 \text{ m}^{-2} \text{ s}^{-1}$), stomatal conductance to water (Gw , $\text{mmolH}_2\text{O m}^{-2} \text{ s}^{-1}$), water use efficiency (WUE , $\text{mmolCO}_2.\text{molH}_2\text{O}^{-1}$), total chlorophyll (Total Chl, $\text{ng mg}_{\text{DM}}^{-1}$), ratio between chlorophyll *a* and *b* (*Chl a/Chl b*), *Fv/Fm* and starch content ($\text{mg.g}_{\text{DM}}^{-1}$) according to the season and drought in 2014 and 2015. Differences between ND and AD were tested with Student tests season by season (mean $\pm$ S.E., $n=5$). Letters denote the difference between treatments for each season with $a > b$.

Table 2 Estimated leaf biomass production (g m^{-2}) in 2014, 2015 and 2016, the increase of DBH ($\text{Increase}_{\text{DBH}}$, in cm.yr^{-1} , difference between DBH in 2015 and 2016) and the leaf mass per area (LMA, g m^{-2}) for autumn 2014 and 2015. These 3 traits were tested with student tests (mean $\pm$ S.E., $n=8$ for leaf biomass; for $\text{increase}_{\text{DBH}}$, $n=146$ in ND plot and $n=52$ in AD plot; for LMA, $n=5$). Letters denote the difference between treatments for each season with $a > b$.

	2014		2015		2016	
	ND	AD	ND	AD	ND	AD

Table 3: Spearman's coefficients of correlations between antioxidants [α -tocopherol, plastochromanol, lutein, β -carotene, neoxanthin and xanthophyll cycle (violaxanthin+zeaxanthin+antheraxanthin, called V+Z+A)], isoprene, phenolic compounds, and physiological parameters [pre-dawn water potential in absolute value (Ψ_{pd}) and net photosynthesis (Pn)] in summer with data from the different years and drought treatments merged together. Coefficients are marked with bold font when correlations were significant at the at least 95% of confidence interval (n=20, *: $0.01 < P < 0.05$, **: $0.001 < P < 0.01$, ***: $P < 0.001$).

Summer	<i>α-tocopherol</i>	<i>plastochromanol</i>	<i>lutein</i>	<i>β-carotene</i>	<i>neoxanthin</i>	<i>V+Z+A</i>	<i>Isoprene</i>	<i>phenolic c.</i>	<i>Ψ_{pd}</i>

Figure 1 Oak Observatory at Observatoire de Haute-Provence (O₃HP). **(a)** Experimental site with the exclusion device opened, **(b)** experimental site with the exclusion device closed (to exclude rain) and **(c)** scheme of O₃HP with the tree repartition in the field.

Figure 2 Ombrothermic diagram for ND and AD between 2012 and 2015. Bars represent mean monthly precipitation (P, mm) and curves represent mean monthly temperature (T, °C) with $P=2T$. Horizontal arrows indicate drought periods (which occur when the temperature curves are above the precipitations bars), vertical arrows indicate field campaigns and dotted arrows at the bottom of the x axis represent the exclusion period (i.e. when rain shelters were deployed).

Figure 3 Cumulative precipitation for ND and AD plots in 2014 and 2015. The dotted line represents the annual mean precipitation calculated for the period 1967-2000 (Santonja *et al.* 2015), which is equal to 830mm.

Figure 4 Autoluminescence imaging of lipid peroxidation in Downy oak leaves. **(a)** Control experiment showing the increase in autoluminescence upon exposure of leaves for 22 h to photooxidative stress conditions at low leaf temperature (HL, 14°C) induced by high PFD ($1800 \mu\text{mol.m}^{-2}.\text{s}^{-1}$). The color scale indicates signal intensity from 0 (black) to saturation (white). **(b)** Autoluminescence imaging of leaves taken from trees under ND and AD conditions in July 2014 and July 2015. Left: picture of the leaves; right: autoluminescence image. **(c)** Quantification of the luminescence signals. The color scale in panel **(a)** indicates signal intensity ranging from 0 (black) to saturation (white).

Figure 5 Leaf concentrations of the tocochromanol-like antioxidants: α -tocopherol **(a, b)** and plastochromanol **(c, d)** in 2014 and 2015, respectively, according to the season and the drought treatment. Differences between seasons were tested with post-hoc Tukey tests and are indicated with different letters (a > b > c). Differences between drought treatments were tested with Student tests, with asterisks indicating significant differences between AD and ND. *: $P < 0.05$ and **: $P < 0.01$. Values are mean $\pm$ S.E., n=7.

Figure 6 Leaf concentrations of the antioxidant pigments lutein **(a, b)**, β -carotene **(c, d)**, neoxanthin **(e, f)** and xanthophyll cycle (violaxanthin+zeaxanthin+antheraxanthin, **g, h**) in 2014 and 2015, according to the season and the drought treatment. Differences between

seasons are tested with post-hoc Tukey tests and are indicated with different letters (a > b > c). Differences between drought treatments were tested with Student tests, with asterisks indicating significant differences between AD and ND. **: $0.001 < P < 0.01$ and ***: $P < 0.001$. Values are mean $\pm$ S.E., n=7.

Figure 7 Emission rates of isoprene (ER isoprene, $\mu\text{gC.g}_{\text{DM}}^{-1}.\text{h}^{-1}$) according to the drought treatments and the season in 2014 and 2015. Differences between drought treatments were tested with Student tests, with asterisks indicating significant differences between AD and ND. Differences between seasons were tested with post-hoc Tukey tests and are indicated with different letters (a > b > c). *: $0.01 < P < 0.05$. Values are means $\pm$ S.E., n=5.

Figure 8 Concentration of total phenolic compounds ($\text{mg}_{\text{eq. gallic acid.g}}^{-1}$) according to the drought treatments and the season in 2014 and 2015. Differences between drought treatments were tested with Student tests, with the absence of asterisks indicating that no significant differences occurred between AD and ND. Differences between seasons were tested with post-hoc Tukey tests with the absence of different letters indicating that no significant differences occurred. Values are mean $\pm$ S.E., n=5.

Figure 9 Principal component analyses (PCA) based on standardized antioxidant concentrations (α -tocopherol, plastochromanol, lutein, β -carotene, neoxanthin, violaxanthin+zeaxanthin+antheraxanthin, isoprene and phenolic compounds) according to the drought treatment and years, by season.
