Received: date / Accepted: date

Abstract The propagation of a planar shock wave through a split channel is both experimentally and numerically studied. Experiments were conducted in a square cross-section shock tube having a main channel which splits into two symmetric secondary channels, for three different shock wave Mach numbers ranging from about 1.1 to 1.7. High-speed schlieren visualizations were used along with pressure measurements to analyze the main physical mechanisms that govern shock wave diffraction. It is shown that the flow behind the transmitted shock wave through the bifurcation resulted in a highly two dimensional unsteady and non-uniform flow accompanied with significant pressure loss. In parallel, numerical simulations using a personal code based on the solution of the Euler equations with a second-order Godunov scheme confirmed the experimental results with a good agreement. Finally, a parametric study was carried out using numerical analysis where the angular displacement of the two channels that define the bifurcation was changed from 90° , 45° , 20° and 0° . We found that the angular displacement does not significantly affect the overpressure experience in either of the two channels and that the area of the expansion region is the important variable affecting overpressure; the effect being, in the present case, a decrease of almost one half.

1 Introduction

In the search for protection from explosions, a variety of underground shelters were studied to minimize the risks related to shock waves propagation in closed area as shown by Ben Dor *et al.* [1] and Igra *et al.* [2]. An important feature in designing such protection is the knowledge of shock or blast wave propagation in ducts leading to the shelter. This knowledge is also of importance for safety precautions in mines, tunnel or corridor after an explosion for protecting humans and materials in case of sudden explosions.

It is therefore not surprising that numerous studies regarding ways to attenuate on-coming shock or blast wave were published during the past fifty years. The propagation of a planar shock wave in a complex ducts system can create serious personal injury and property damage due to numerous reflections which generate local zones of dangerous high-pressure. Thus, the knowledge of the generated flow field and wave evolution is essential for engineering treatment of explosion-related phenomena.

As stated above, many studies were conducted in the 1950s on the propagation of shock waves through ducts having small area changes, *e.g.*, Chester [3], Laporte [4], Chisnell [5] and Whitham [6]. A detailed theoretical treatment is given concerning the diffraction of plane shock waves and its impact on the shock strength and the shocked flow. We learn that the wave pattern of the transmitted shock wave in a contraction or an expansion is dependent on various factors like the ratio of the areas or the incident shock wave Mach number. These studies show some major differences between the behavior of the transmitted shock wave depending on whether there is supersonic or subsonic flow behind the incident shock wave. Straight duct investigations with changing areas were continued by Nettleton [7], Salas [8] and Igra *et al.* [9]. Further, studies of shock waves propagation through ducts having significant direction changes were undertaken

by Heilig [10], Skews [11] and Igra *et al.* [12, 13]. Assigning significant direction changes along the way of the shock wave leads to important shock attenuations due to losses through the numerous reflections and diffractions applied to the shock. All these experimental and numerical investigations show that the flow developed behind an initially planar shock wave propagating through a tunnel system, is complex two-dimensional unsteady and non-uniform. In such closed area systems subjected to an explosion, the induced shock wave inevitably meets numerous bifurcations. Thus, the understanding of shock wave propagation through a split channel is needed. The present paper provides an experimental and numerical investigation of shock wave propagation through a 'Y' bifurcation having a constant cross section as shown in Fig.1. The study focuses on the shock wave evolution and pressure histories recorded and computed along the 'Y' device.

The first part of this work is experimental and provides a qualitative explanation on the propagation of the incident shock wave and the flow field behavior behind it for the three Mach numbers investigated and, gives a qualitative analysis of the attenuation generated by the Y-shaped configuration. Indeed, one major objective of the study is to reduce the risks related to the shock wave propagation and so, minimize pressure levels along the branches and reflecting on the end-wall.

The second part is based on numerical calculations, it completes the experimental investigation of the flow field in the device by adding some main physical mechanisms that only a numerical analysis could afford. This analysis includes a numerical shadowgraph of the flow field behind the shock which highly depends on the incident Mach number.

Finally, a numerical parametric study on the bifurcation angle ' α ', from 90° to 0° , and its impact on the end-wall reflected pressure in the domain is also conducted.

2 Experimental setup

Experiments were conducted at the IUSTI laboratory using a horizontal shock tube having a constant square cross section ($80 \times 80 \text{ mm}^2$). Details regarding this shock tube can be found in Jourdan *et al.* [14]. At the end of the shock tube a 'Y' shape duct was added as shown in Figs 1 and 2. One of the original aspect of this study is the modularity of the device. It was designed using a 'block technology' allowing for a modular assembly. In this way, we can realize different ducting systems by using the same set of blocks as illustrated in Fig.2. We remind that in the present work only the Y-shaped duct is explored but that other configurations will be the object of further research.

The test gas in the driven section was air at standard conditions, 298K and 1.01325 bar. Different shock wave Mach numbers were tested, a weak one ($M=1.12$), a shock of medium

strength ($M=1.36$) and a stronger one ($M=1.69$). High pressure and low pressure sections are initially separated by an aluminum diaphragm and the driver section is further filled with air ($M=1.12$ and 1.36) or helium ($M=1.69$) to burst the diaphragm. The incident shock wave Mach number was experimentally deduced from pressure records (PCB 113B26) taken at two different locations along the shock tube wall (see C6 and C1 in Fig.1). The Y-shaped duct was also equipped with six piezo-electric pressure transducers (PCB 113B28) numbered from M1 to M6. Which are connected to a multi-channel digital oscilloscope (Tektronix DPO4054) through PCN amplifiers (482A22 type). The schlieren system used here is a standard Z-type schlieren setup with two concave mirrors on either side of the test section. A 400W Tungsten lamp (from a Dedolight Daylight HMI Spotlight) combined with a condenser is used as a bright white source of light. The light is passed through a horizontal slit (5 mm width) which is placed at the focal point of the first mirror such that the reflected light from the mirror forms parallel rays that pass through the test section. On the other side, the parallel rays are collected by the second mirror and focused to its focal point at a horizontal knife edge (sensitive to density gradients in vertical direction). The rays continue on to a Fastcam SA1 video camera. This light source is a continuous-wave (CW) light source not well-suited for short-duration use. However, with the camera having an electronic shutter operating independently of the frame rate selected, it is possible to impose an exposure time of $1/1\,000\,000 \text{ s}$ and to minimize the motion blur. The flow field was monitored with a frame rate of 40,000 frames per second (fps) and a spatial resolution of 512×256 pixels which corresponds approximately to about 0.625 mm/pix .

During each run, a sequence of schlieren pictures and some pressure histories were recorded at a pre-set time delay in order to cover the entire flow duration of about 3 ms. Triggering of the measuring instruments was done when the incident shock wave reached the sensor located in station C6. The 300 mm diameter viewing area focuses on the bifurcation point. Other details including pressure gauge locations are shown in Fig.1. It must be noted the presence in the device of the parameter called α corresponding to the angle between the shock tube main channel axis and the bifurcation. That parameter is fixed in the experimental case but varies from 90° to 0° in the numerical study.

3 Numerical modelling

The flow field can be modelled by the Euler equations that express conservation of mass, momentum and energy for an inviscid compressible fluid obeying a perfect gas equation of state. For a two-dimensional non-stationary flow, the conser-

Fig. 1 Scheme of the experimental setup: the T80 shock-tube, the Y-shaped test section and the pressure transducers arrangement.

Fig. 2 Schemes and photography showing the modularity of the test section in a) Y-shaped, b) 90° bend, c) cross-sectional enlargement d) 45° angular deviation and e) Abrupt area change configurations.

variation equations, expressed in Cartesian coordinates, are:

$$\frac{\partial U(\vec{x}, t)}{\partial t} + \vec{\nabla} \cdot F(U(\vec{x}, t)) = 0 \quad (1)$$

where,

$$U = \begin{pmatrix} \rho \\ \rho \vec{u} \\ \rho \cdot e \end{pmatrix}, F(U(\vec{x}, t)) = \begin{pmatrix} \rho \vec{u} \\ \rho \vec{u} \vec{u} + p \cdot I \\ (\rho \cdot e + p) \vec{u} \end{pmatrix} \quad (2)$$

$$e = \varepsilon + \frac{u^2}{2} \quad (3)$$

$$p = (\gamma - 1) \rho \varepsilon \quad (4)$$

U is the vector of conservative variables at location x and time t , F is the flux vector. $u, \rho, p, e, \varepsilon$ are velocity components (along the x and y directions), density, pressure, total energy and internal energy respectively. $\gamma > 1$ is the specific heats ratio.

The discretization of this problem is a volume finite discretization which integrates the equation (1) on a volume V . This contour C is made up of N faces defined by their contour C_k , their area A_k and the normal vector \vec{n}_k . The flow values, U and F , are considered to be constant on each area A_k .

With the definition $U_i^n = \frac{1}{V_i} \int U(\vec{x}, t) dv$, we can write the Godunov numerical scheme:

$$U_i^{n+1} = U_i^n - \frac{\Delta t}{V_i} \sum_N A_k \vec{F}_k \vec{n}_k \quad (5)$$

The calculation of the flux vector F is based on the resolution of the Riemann problem between U_i^n and U_{i+1}^n . This scheme is extended to a second-order using the method of MUSCL-Hancock [15]. It is submitted to a stability criterion which allows to define the time stepping:

$$\Delta t < \frac{dL}{\|u\| + c} \quad (6)$$

$\|\vec{u}\|$ corresponds to the local flow velocity, c is the local sound velocity and dL the minimal length characterizing the volume V . Details regarding this numerical scheme and its extensions are given in Thevand *et al.* [15].

4 Results and discussion

4.1 Experimental waves pattern

Sets of experiments have been conducted under three different Mach numbers and the results are further compared with numerical simulations. The representative experimental schlieren sequences showing the propagation of shock waves having respectively a Mach number of 1.12, 1.36 and 1.69 through the Y-shaped bifurcation are presented in Figs 3, 4 and 5. The incident shock wave initially generated in the main channel of $80 \times 80 \text{ mm}^2$ square cross section propagates from left to right in the 'Y' closed device. The time (in milliseconds) appearing on each picture indicates the time that has passed since the incident shock wave reached the C6 station (Fig.1) in the main channel. It should be noted that only the incident shock is represented in the different schlieren sequences, from the area visualization beginning to the end (300 mm diameter circle). That means the two end-wall reflected shocks cannot be seen. Finally, note that we used as window two plates of Plexiglas of 40 mm thick as shown in Fig.1. Then, the optical quality, the thickness and the unperfect parallelism of the plates can be the origin of the dark region in the upper right corner. About lines visible in Figs 3, 4 and 5 it is probably due to the horizontal noise present on the camera sensor and not corrected with the shading procedure.

In Fig.3, during the investigated time, about 1.5 ms, we see the early part of the interaction between the transmitted and the reflected shock waves through the bifurcation. Specifically, at $t=2.875 \text{ ms}$ the incident shock wave reached the peak of the Y-shaped duct. Upon its exit from the shock tube, the incident shock loses its planar shape due to its interaction with the expansion waves, located at the two corners of expansion zone, and turns to a curved shock. The expansion zone corresponds to the area between the end of the shock tube main channel and the peak of the Y-shaped duct bifurcation. The expansion waves that we are talking about are generated in this location by the diffraction of the shock wave which leads to the formation of two recirculation zones and expansion waves because the pressure decreases locally. These phenomena will be detailed further. In the considered case ($M=1.12$) the flow deflection angle, caused by the Y-shaped duct results in a regular reflection; see Fig.3 at $t=2.925, 2.975$ and 3.025 ms . This will not be the case once the incident shock wave Mach number increases. Finally, the reflected shock wave from the bifurcation go back upstream in the main channel shock tube.

Fig. 3 A sequence of schlieren photographs showing an initial planar shock wave, of Mach number of 1.12, propagating from left to right through the 'Y' bifurcation.

Results shown in Fig.4 are for $M=1.36$ and it is clear from $t=2.40 \text{ ms}$ to 2.50 ms , the reflection from the Y-shaped duct is a Mach reflection. More specifically, as shown in Bendor's work [16], such a reflection is called a single-Mach reflection. The triple point linking the reflected shock wave from the peak of bifurcation, the transmitted shock wave which propagates in the branch and the stem Mach can be seen. Furthermore, in this case, we can observe on the two last pictures the interaction of the shock wave reflected from the Y-shaped duct with the walls. The strong flattening of the reflected shock wave observed from $t = 2.5 \text{ ms}$ to $t=2.6 \text{ ms}$ can be explained by the fact that the shock wave is moving into oncoming flow, but because it is approaching the flow at different angles, that affects its velocity, slower at the symmetry line because it is approaching incoming flow directly while at the two corners, it is at an angle. Thus, the shock wave is stretched out becoming more planar. At $t=2.6$

Fig. 4 A sequence of schlieren photographs showing an initial planar shock wave, of Mach number of 1.36, propagating from left to right through the 'Y' bifurcation.

ms, as for the low Mach number case, the reflected shock wave from the Y-shaped duct is just about to enter the shock tube main channel while the shocks reflected from the upper wall of the Y-shaped duct are progressing toward the lower wall. These three shocks collide with the two centered rarefaction waves creating a zone of highly non-steady and turbulent flow. Such multiple interactions reduces the energy contained in the flow and eventually will reduce the pressure acting on the secondary channel end-wall as will be shown subsequently.

Increasing the incident shock wave Mach number will further intensify the observed flow field as evident in Fig.5, where the incident shock Mach number is 1.69. Again a Mach reflection is observed (see at $t=1.95$ ms and $t=2$ ms). Thereafter the wave pattern is amplified with respect to that observed in the previous case (in Fig.4). We have to note that, while in the previous two cases both the driver

Fig. 5 A sequence of schlieren photographs showing an initial planar shock wave, of Mach number of 1.69, propagating from left to right through the 'Y' bifurcation.

and the driven gases were air, in the present case ($M=1.69$) the driver gas is helium. Consequently, the sound speed being almost three times higher in helium than in air, the expansion waves reflected from the driver's end-wall catch up the incident shock wave before it enters the test section. The usual constant pressure plateau triggered behind a normal shock wave is here different and looks more like a blast wave signal with a peak of pressure followed by a decrease (see Fig.6). Indeed, the constant pressure case is a special case for flow in shock tubes with constant cross section area where the expansion fan has not yet caught up the incident shock wave.

Figure 6 represents the superposition of the whole shock tube and the pressure distribution for three different times. Respectively, the red, the green and the purple lines correspond to the pressure distribution along the shock tube represented, at the instant of the diaphragm rupture, when the shock wave has traveled half part of the driven section and when it reaches

Fig. 6 Numerical signal pressure along the shock tube with helium as driver gas for $M=1.69$.

the C6 gauge station. We can clearly see the drop of pressure behind the shock wave during its propagation. The present case which required Helium as driver gas to experimentally reach a Mach number of 1.69 will not numerically be repeated in the following where the driver and the driven gases are air.

4.2 Signal pressure evolutions

When choosing a special duct geometry for reducing the strength of the transmitted shock, a good way to assess its performance is by comparing the overpressure acting on the closed end-wall (ΔP_1 and ΔP_4 at stations M_1 and M_4) of the considered geometry with a reference defined as that prevailing in a similar straight duct (ΔP_r in Fig.7.) as schematically shown in Fig.7.

In the investigated channels, pressure gauges M_1 and M_4 recorded the closed end-wall pressure; obtained results are shown in Fig.8 (black and red line for ΔP_1 and ΔP_4). It is apparent from this figure that in the cases where the incident shock wave Mach number was either 1.12 or 1.36 the expected constant pressure behind the reflected shock is evident. This is no longer the case when the incident shock wave uses helium as the driver gas ($M=1.69$).

However, whatever the considered case, it is clear that the pressure acting on the end-wall of a Y-shaped duct is less than half of that acting in a similar end-wall of a straight duct.

Fig. 7 Schematic representation of the reference (a) and the Y-shaped duct (b) geometries.

Fig. 8 Overpressure histories recorded behind the reflected shock wave off the end-wall for each branch of the Y-shape section (M_1 and M_4) compared to that recorded at the end-wall of the main channel (ΔP_r) without the test section for Mach numbers of 1.12 (a), 1.36 (b) and 1.69 (c).

4.3 Numerical validation

The physical model previously presented is now compared to the experimental results both qualitatively (wave patterns in Fig.9) and quantitatively (pressure signals in Fig.10). Fig.9 presents a comparison of schlieren pictures (experimental versus numerical) taken at same time (corresponding to Fig.4 at $t = 2.45$ ms). The schlieren variable calculated in the present work is the magnitude of the density gradient computed at each cell and visualized using open source Paraview software. Specifically, the numerical schlieren is calculated here as follows.

$$S_n = \log_{10}(1 + |\vec{\nabla}\rho|) \quad (7)$$

In view of the complexity of the present flow in the vicinity of the bifurcation, we can reasonably consider the numerical calculation in good agreement with the experimental observations. Fig.10, comparisons of pressure signals obtained experimentally and numerically for an incident shock wave Mach number of 1.36 are shown for several sensor locations (M1, M2 and M4). Fig.10 shows that no significant difference (less than 5% on the recorded mean value) exists between numerical and experimental pressure traces. Only, the first peak of pressure shows a somewhat larger difference certainly due to the slightly error between the experimental and numerical sensor location. Note that the experimental values of the end-wall reflected pressure are slightly below the numerical ones and can be explained by the non ideal experimental conditions as calibration of sensors, parasitic losses in the device, small leaks or unperfect initial experimental condition.

4.4 Numerical simulation results

As seen earlier, a flow analysis based on the experimental schlieren photographs (see part 4.1) has been established. Nevertheless, available experimental data do not provide all the necessary information to properly understand the flow field. Indeed, the viewing area is limited to 300 mm and only gives access to the flow wave pattern. In complement to this description, a numerical map of the flow behind the shock wave through the bifurcation has been established, in order to show some complex phenomena which appear with increasing velocity of the incident shock wave. Moreover, it can help to answer questions such as, what happens when the incident shock wave passes through the expansion zone? At what incident Mach number the flow behind the shock wave becomes supersonic and does it change the flow behavior along the device? Does the incident shock wave become planar again after the bifurcation? Numerical calculations allow us to efficiently respond to these questions.

It is known that shock diffraction occurs when a plane shock encounters an area increase (expansion) in flow and the details thereof. This can be found in some of the references cited such as [3], [5], [7]. Thus, when the incident shock wave reaches the expansion zone, the flow generates two recirculation zones, located at the two corners, where the pressure is locally reduced and the velocity increased. These results are confirmed in this case in Fig.11.

Now, we focus on the appearance of the first supersonic zone in the flow field behind the incident shock wave to see if it has an impact on the flow behavior. The area of the Y-shaped duct where the flow behavior is the more complex is located between the expansion zone and the angle of the bifurcation. Skews's work [17] describes the behavior of the disturbances produced in the region perturbed behind

Fig. 11 Flow pressure (top, bar) and flow Mach number (bottom) behind the shock wave in the expansion zone of the Y device, 2.30 ms after the incident shock wave reaches the C6 station, for a shock wave Mach number of 1.36.

Fig. 12 Scheme of the area studied with the line 'L' along which the flow field Mach number is calculated

a diffracting shock wave. We are in a similar case of diffraction but only in the very first instant after the incident shock wave enters in the expansion zone because of the bifurcation point acting like an obstacle. At the time when the incident shock wave meets the bifurcation point the problem is no longer the same. As a similar manner we will focus on the appearance behind the incident shock wave of supersonic and subsonic zones in the expansion zone and the bifurcated branch by increasing the incident shock wave Mach number. Thus, we decided to study the evolution of the flow Mach number over time and along a line across this zone as described in Fig.12. The line 'L' is placed at 1 mm from the top wall of the bifurcated branch. While the fact that the velocity flow behind the incident shock wave increase near the corner is evident (zone '1' in Fig.13.a) it is less obvious that this acceleration zone is replaced by two acceleration zones (zones '3' and '4' Fig.13.c.) separated by a canal of zero speed (zone '2' Fig.13. b. and c.). We will see further that these acceleration and zero speed zones will give way to a very complex map of supersonic and subsonic zones in the 'Y' device by increasing the Mach number. We conducted

Fig. 13 Zoom of the expansion zone representing the flow Mach number and the corresponding plot along the line 'L' for an initial Mach number equal to 1.12. for $t=2.975$ ms (a), 3.325 ms (b) and 3.4 ms (c).

the same study for the two other Mach numbers (1.36 and 1.69). The major difference between the previous case (1.12) and the one explained in Fig 14 (1.36) is that the two acceleration zones '1' and '3' are now supersonic as we can see in Fig.14 b. It seems to be important to note that in this case the flow behind the shock wave switch from subsonic to supersonic by entering the expansion zone. Thus, we have direct transitions between supersonic and subsonic zones, which cannot be possible without the formation of shock waves. We also see in this case the formation of another supersonic zone labelled '5' which seems to separate from the zone '4' (Fig.14 b. and c.). The flow along the 'L' line crosses consecutively two shock waves, twice in a row. Fig.15 represents a numerical sequence of schlieren photographs showing the propagation of the shock wave along the 'Y' (Mach 1.36). It is clearly shown the apparition of these shock waves in the expansion zone. Moreover it shows that the reflected shock wave from the point of bifurcation propagates upstream the general flow motion. By increasing the strength of the incident Mach number (1.69), all these mechanisms are repeated and amplified as it is subsequently shown. Fig.16 presents the evolution of the flow Mach number along the line 'L'. We can see that the mechanisms are similar to the previous case ($M=1.36$) but amplified. The mapping of this area

Fig. 14 Zoom of the expansion zone representing the flow Mach number and the corresponding plot along the line 'L' for an initial Mach number equal to 1.36. for $t=2.45$ ms (a), 2.625 ms (b) and 2.875 ms (c).

Fig. 16 Zoom of the expansion zone representing the flow Mach number and the corresponding plot along the line 'L' for an initial Mach number equal to 1.69. for $t=2$ ms (a), 2.1 ms (b) and 2.2 ms (c).

Fig. 15 Numerical sequence of schlieren photographs, for a shock wave Mach number of 1.36.

shows the flow field is also covered by supersonic and subsonic zones separated by shock waves. The zones '4' and '5' in Fig.16 c. are now separated by another subsonic canal that leads to the formation of a new shock wave allowing the transition between these two supersonic zones. A particularity in this case is the border between the zones '1' and '4' which are both supersonic but whom the transition is discon-

Fig. 17 Zoom on the expansion zone representing the shocked flow Mach number and the corresponding plot along the line 'L*' for an initial Mach number equal to 1.69 (see Fig.16.c.).

tinued as we can see in Fig.17. Indeed, the line along which the flow Mach number is calculated is now shifted in order to cross the zones '1', '4' and '5'. The plot of the flow Mach number along the line ('L*' located 30 mm away from the top wall) clearly shows the discontinuity between the two supersonic zones ('1' and '4' in Fig.16. c.) and the subsonic canal between '4' and '5'.

In the previous case, for $M=1.36$, the flow is highly perturbed by entering in the expansion zone and because of the reflection of the incident shock wave on the bifurcation point but none of these phenomena remains stationary. It is not the

Fig. 18 Numerical sequence of schlieren photographs for a shock wave Mach number of 1.69.

case for a stronger incident shock wave ($M=1.69$). Fig.18 presents a numerical sequence of schlieren photographs of the shock wave propagating in the Y shaped duct ($M=1.69$). We can observe in the expansion zone the creation of quasi-stationary shock waves.

Indeed, in the previous case ($M=1.36$) the reflected shock wave from the bifurcation point could move upstream, but now it is no longer the case. We clearly see that this reflected shock wave is now stuck in the expansion zone and stationary, as with the other shock waves present in the flow.

Fig.19 corresponds to the superposition of the schlieren density and the Mach number of the flow behind the incident shock wave having a Mach number of 1.69 just before it reaches the end wall. The matching between, the alternately subsonic and supersonic zones and the presence of stationary shock waves is obvious. Lastly, the incident planar shock wave which curves upon its exit from the shock tube becomes planar again along the Y branches despite the highly non-steady zones as we can see in Fig.19.

Finally, we have seen that the coupling between the diffraction on the incident shock wave with its reflection on the bifurcation point leads to the appearance of acceleration and deceleration zones inside the bifurcation. These zones become at first subsonic and supersonic by increasing the incident shock wave ($M=1.36$) and seem to become almost stationary by further increasing the Mach number (1.69).

4.5 Parametric study - Influence of the angular variation

As shown in Figs.9 and 10, a very good agreement exists between experimental records and the simulations when the angle α between the shock tube main channel axis and the bifurcation duct, is equal to 45° (see Fig.20). Therefore, a

Fig. 19 Numerical superposition of the schlieren density and the flow Mach number just before the incident shock wave ($M=1.69$) reaches the end wall.

numerical parametric study has been realized by changing respectively α from 90° to 0° (90° , 45° , 20° , 0°) which corresponds in this last case to an abrupt opening of the straight duct as schematically represented in Fig.20. The geometry of the abrupt area change configuration was chosen in keeping the same study volume than with the Y-shaped one and keeping the same expansion area ratio equal to two. This analysis which compares for the four geometries the pressure behind the end-wall reflected shock wave, indicates that the change of α has almost no influence on the pressure. It appears that the end-wall reflected pressure calculated in each geometry and for the three Mach numbers studied (1.12, 1.36 and 1.69) are nearly identical as presented in Table1.

Fig. 20 Schematic drawing of the numerical devices for the parametric study.

Mach Numbers	End-wall reflected overpressure (bar)			
	(a.) 45°	(b.) 20°	(c.) 0°	(d.) 90°
1.12	0.475 bar	0.480 bar	0.482 bar	0.414 bar
1.36	1.670 bar	1.707 bar	1.730 bar	1.612 bar
1.69	4.349 bar	4.459 bar	4.485 bar	4.339 bar

Table 1 Numerical end-wall reflected overpressures for the three geometries and for shock wave Mach numbers 1.12, 1.36 and 1.69.

Thus, the present results clearly show that the angle of the bifurcation has no impact on the end-wall reflected pressure and then on the attenuation of a shock wave propagating through a ducts system. A conclusion which can directly be drawn from this investigation is that the leading parameter which strongly impacts the attenuation of the incident and the reflected shock wave is the enlargement of section and not necessarily the complexity of the duct geometry. Indeed, in all the configurations explored here we have an increase in the cross-section area with a ratio equal to two, which leads to highly reduce the reflected pressure in comparison with the case of a shock wave propagating in a straight shock tube at same condition (see part 4.2). But the value of this attenuation is practically the same in each case and confirms that the expansion ratio of the section area is the preponderant parameter compared to the propagation way of the shock wave. Note that experiments with an abrupt opening configuration (case c. in Fig.20) were also conducted and results obtained also show a very good agreement with the numerical simulations as shown in Fig.21 for an incident shock wave Mach number of 1.44.

Fig. 21 Comparison of the experimental and numerical overpressure histories recorded behind the reflected shock wave off the end-wall for the abrupt opening configuration and for an incident shock wave Mach number of 1.44. The red and the black lines correspond to the experimental and the numerical records, respectively.

5 Conclusion

The flow field and the wave patterns developed inside a Y-shaped duct connected to the end of a conventional the shock tube was both experimentally and numerically studied. A detailed description of the wave pattern is given for three different Mach numbers. It is shown that very good agreement exists between recorded wave evolvement and their simulation; as well as between recorded pressure histories and appropriate simulations. Therefore, the presently used physical model and its numerical solution could safely be used for similar ducts to be proposed for shock/blast wave attenuation. The numerical tool allowed us to establish a map of the flow field behind the incident shock wave in order to describe some main physical mechanisms not available in the experimental investigation as the appearance of supersonic zone in the expansion area. It is shown that the pressure prevailing behind the reflected shock wave from the end-wall of the Y-shaped duct is less than half of what exists behind a reflected shock wave from a similar straight duct under the same initial conditions. Thereby such duct geometry is a suitable proposal for significantly reducing the potential danger damage of a travelling shock blast wave in tunnels. Moreover, we also have seen that the expansion ratio of the cross-section area is a preponderant parameter in attenuating the strength of a shock wave compared to the duct geometry.
