ABSTRACT

In this work, the Supercritical AntiSolvent (SAS) process has been used to generate micronized crystals of Sulfathiazole (STZ) from different organic solutions, namely acetone, acetonitrile, tetrahydrofuran and acetic acid. The flow rates of CO₂ (2–21 g min⁻¹) and of the organic solution (0.19–6 mL min⁻¹), as well as STZ concentration in the organic solution (20–70% under the saturation), have been varied to identify the conditions leading to powders exhibiting only one polymorphic form. Pressure (10 MPa) and temperature (313 K) have been kept constant. In this paper, thermodynamic and hydrodynamic aspects are discussed so as to rationalize the obtained crystal characteristics and provide a new way to control the SAS process applied to drug pre-formulation. The influence of the organic solvent nature on both the polymorphic form and the habit of generated crystals, has been particularly discussed.

1. Introduction

Crystallization processes involving a supercritical medium are gaining momentum as they are regarded as environmentally friendly processes and allow good control over product properties, especially particle size, Particle Size Distribution (PSD), crystal habit and polymorphic form. This is mainly because crystallization processes using sc-CO₂ often involve only one crystallization step, unlike conventional methods of crystallization in solution. CO₂ being gaseous at ambient conditions of pressure and temperature, the separation of CO₂ from the

end-products is spontaneous and does not require successive separation operations. Thus, a single-step process or a process involving a reduced number of steps will lead to the formation of powders with homogeneous characteristics. When a series of steps is involved, the size as well as the habit or the polymorphic nature of the crystals may evolve. The good control of powder characteristics using supercritical fluids is also due to the large number of operating parameters and conditions (pressure, temperature, hydrodynamics and mixing conditions, supersaturation level, etc.) that can extensively be varied, therefore allowing efficient screenings for particle drug design. Amongst the different

supercritical processes, the Supercritical AntiSolvent (SAS) process, using supercritical carbon dioxide (sc-CO₂) as crystallization anti-solvent, brings particular interest for drug reprocessing [1–9], that are often sparingly soluble into sc-CO₂.

Crystallization during the SAS process is both induced by the sc-CO₂ antisolvent effect and by the organic solvent depletion. When the organic solution containing the solute to recrystallize and sc-CO₂ are put in contact, the organic solvent diffuses into the CO₂-rich phase while CO₂ diffuses into the organic solution-rich phase, quickly leading to solute supersaturation in the organic solution's expanded phase. Crystal size is often at the micron or sub-micron order of magnitude thanks to the rapid transfer phenomena in supercritical media, which represents one of the most important assets of this technology.

This paper presents an experimental application of drug reprocessing by SAS, using Sulfathiazole (STZ) as the solute to be recrystallized. This compound, a veterinary drug, has a complex drug behavior regarding its ability to crystallize into five known polymorphic forms [10]. For that criterion, it has been widely described in literature either for crystallographic investigations [11–15] or for crystallization behavior into both liquid phases [16,17] or supercritical media [18–20]. It is worth noting that different nomenclatures exist for the five polymorphic forms of Sulfathiazole. In this study, the nomenclature proposed by Apperley et al. has been adopted [13]. A brief description of the five crystal cells and their *Cambridge Structural Database* (CSD) reference are given in Table 1.

Two forms are commonly observed throughout experimentations, namely so-called forms I and IV. At ambient conditions, the relative stability is IV > I. Furthermore, Munroe et al. [21] investigated the relative stabilities of the five polymorphs of Sulfathiazole depending on the temperature. It appears that, from 283 K up to 323 K at atmospheric pressure, polymorphic form I is the least stable of all five forms, then this order follows: I < II < V < IV < III.

Commonly, process development around drug particle generation consists in optimizing the drug bioavailability by reducing its size, narrowing its size distribution and controlling both crystal habit and polymorphism. As mentioned above, the SAS process can be tuned to target given specific properties of the end-product. Temperature, pressure, solute concentration in the feeding solution and flow rates of both CO₂ and organic solution phases are commonly screened parameters [22]. Erriguible et al. [23] proposed a complete 3D simulation of the SAS process by varying operating conditions in a range of typical target conditions. They have investigated the crystallization of a solution of minocycline-ethanol and predicted a reduction of particle size by decreasing the solid-fluid interfacial tension as well as by increasing the initial concentration in the feeding solution or by increasing the injection jet velocity. Estimation of the interfacial tension has been reported as of major interest to consider the simulation as a predictive tool. Jet dispersion conditions of the organic solution were reported as a significant criterion to control particle characteristics by Petit-Gas et al. [24]. They have studied the crystallization of a solution of STZ-acetone in SC-CO₂. Finer particles of STZ were obtained for higher jet velocities, but also with larger capillary internal diameter at a constant jet velocity. Furthermore, different morphologies were observed, corresponding to different polymorphic forms of STZ crystals, for different Reynolds number values of the organic solution. Careno et al. [25] and

Boutin et al. [26] studied alternative injection technology, namely impinging jets and concentric tubes, to greatly enhance phase mixing and mass transfers, thus reducing crystal size, for STZ-acetone and STZ-methanol systems. Other enhanced mass transfer conditions were successfully achieved for the SAS process, by atomizing the liquid jet on a vibrating surface at an ultrasonic frequency [27] (Griseofulvin-dichloromethane and Griseofulvin-tetrahydrofuran systems) or by stirring [28] (Griseofulvin-acetone system). As for conventional recrystallization methods in solution, the organic solvent nature has also been reported as one of the most significant factors that control the SAS process and crystal habit. It has been proven that changing the organic solvent [29,30], or adding a growth inhibitor [31], may modify the crystal habit without modifying its crystal structure. A probable explanation is that the growth of one crystal's face may be selectively slowed down in comparison to the others due to solvent-or growth inhibitor-adsorption, which depends on the interaction between the solvent molecules and the solute molecules on crystal faces.

However, predicting and controlling the polymorphic form of the solute crystals has been less extensively studied. Kordikowski et al. [32] showed in the case of STZ recrystallized from acetone, that the flow ratio (CO₂/acetone) has a preponderant role influencing the polymorphic form, whilst temperature has a preponderant role in the case of STZ reprocessed from methanol. The polymorphic form of STZ has therefore been related to the choice of solvent. Bouchard et al. [33] highlighted a strong dependence of glycine polymorphic form behavior on both the solute concentration into the feed and the ethanol fraction in the CO₂-rich phase. The form IV is obtained for higher solute concentration and lower ethanol fraction, thus for higher supersaturation values. Later, Rossmann et al. [34] investigated the case of paracetamol, concluding that varying the solvent nature, in this case acetone, ethanol and a mixture of both, can lead to a modification of the crystalline form.

In this work, SAS process experiments were carried out at constant temperature (313 K) and pressure (10 MPa), but organic solution and sc-CO₂ flow rates, STZ concentration and organic solvent nature were varied with the aim of obtaining powders exhibiting only one polymorphic form. Thirteen solvents exhibiting different polarity and proticity properties were tested in a preliminary solubility measurement study at ambient pressure. Among them, four were retained for the SAS experiments according to their solvent power regarding STZ: acetone, acetonitrile, tetrahydrofuran and acetic acid. Solubility measurements of STZ in the four selected organic solvents were performed to evaluate the saturation degree of the initial organic solution used for the SAS process. The powders were characterized by ¹³C Nuclear Magnetic Resonance (NMR) to determine the nature of the polymorphic forms obtained pure or in mixture. Pure crystalline powders in terms of polymorphic form were also observed by Scanning Electron Microscopy (SEM). Crystal characteristics were then discussed by considering the varied operating conditions corresponding to different thermodynamic and kinetic conditions.

purchased from Sigma-Aldrich, France; Acetonitrile was purchased from VWR; Acetic acid was purchased from Fisher, France. All chemicals were purchased at purity $> 98\%$ and were used without further purifications. Carbon dioxide (purity of 99.7%) was purchased from Air Liquide, France.

2.2. Solubility measurements procedure

STZ and organic solvent are mixed together with a magnetic stir bar in a sealed container with an intentional excess of solute. The container is placed in a temperature bath regulated at 313 K. After several hours, the agitation is stopped and a part of the supernatant is collected with a syringe equipped by a millipore filter (VWR – 0.45 μm). This sample is immediately diluted in a weighed quantity of pure solvent to prevent the crystallization from occurring through cooling. The concentration of the diluted solution is given by density measurement, referred to a calibration curve, with a density meter DMA 5000 M Anton (precision of $10^{-6} \text{ g cm}^{-3}$), at 293 K.

2.3. Experimental set-up for SAS process

The experimental apparatus used for this study is detailed in Fig. 1. It includes a 480 mL (internal diameter: 60 mm) double jacket autoclave (TOP INDUSTRIE, France). The maximum allowable pressure is

25 MPa at a temperature of 423 K. It is equipped with pressure and temperature sensors, as well as an 18 MPa rupture disk. The fluids, namely CO₂ and organic solution, are injected at the top of the autoclave thanks to two high pressure liquid piston pumps (SEPALEX, France and GILSON, France, respectively for CO₂ and organic solution). Organic solution feed is injected through a 127 μm internal diameter capillary tube. CO₂ flow is measured thanks to a Coriolis Effect flow-meter (BRONKHORST, France). A frit filter (2 μm) and a glass fiber filter (1.2 μm) are placed at the bottom of the autoclave to retain and easily collect generated particles. A cold solvent trap allows the separation of exiting fluids: CO₂ is evacuated and organic solution is recycled.

2.4. Experimental procedure

A first step consists in stabilizing the composition in the autoclave at the target conditions by injecting CO₂ and pure solvent. The target pressure and target temperature have been respectively fixed at 10 MPa and 313 K to ensure monophasic conditions. When the target conditions are reached, exit valves are open and the operating conditions are stabilized. Then, pure solvent feed is replaced by the organic solution, containing the solute to be crystallized. The solute concentration is given as a fraction of the organic solution saturation at 313 K, noted β_{OS} .

From that time on, sc-CO₂ has an antisolvent role. CO₂ and organic solvent reversediffusion occurs due to concentration gradient, causing a rapid and large supersaturation, thus a fast crystallization.

The generated particles are retained at the bottom of the autoclave. At the end of the injection step, the injection line is washed with pure solvent to avoid nozzle clogging, then the organic solvent flow is stopped. The CO₂ flow is kept so as to renew the fluid phase content in the autoclave and dry the crystalline powder, from 3 up to 5 residence time. At the end of these washing steps, the autoclave pressure is dropped to atmospheric pressure and the powder that has been accumulated on the filter is collected.

The experimental conditions tested in this work are listed in Table 3 (see part 3.2). Feed flows of both phases as well as STZ concentration into the organic solution were varied to identify which operating conditions allow the formation of pure powders in term of polymorphic form, for each studied solvent, namely acetone (Acet), acetonitrile (ACN), tetrahydrofuran (THF) and acetic acid (AcAc). CO₂ and organic solution flow rates were varied from 2 up to 21 g min^{-1} and from 0.19 up to 6 mL min^{-1} respectively. Thus, solvent to CO₂ molar ratios ($X_{\text{solvent}}/\text{CO}_2$) were varied from 5 up to 23 mol%.

2.5. Polymorphic form characterization using ¹³C NMR

Each crystal powder was analyzed to determine the polymorphic form, or the composition of polymorph mixtures, of generated particles. X-Ray Diffraction is a commonly encountered method, but can lack precision when it comes to quantitative analysis. In this work, solid-state Nuclear Magnetic Resonance was chosen for both the qualitative and quantitative analysis of STZ powders, using a BRUKER AVANCE III 400 MHz spectrometer, working at a ¹³C resonance frequency of 106 MHz. Characteristic NMR signals for STZ are taken from Apperley et al. [13].

2.6. Particle observations by SEM

Generated crystals are observed with a Scanning Electron Microscope to determine the crystal habit for each observed sample. Moreover, particle size and the size distributions were determined for the samples exhibiting only one polymorphic form. SEM observations were performed thanks to the JEOL JSM 6320-F device, working with a field emission gun. A metallization step with a gold plasma for 90 s was performed before each observation.

3. Results and discussions

3.1. Solubility of sulfathiazole into organic solvent

STZ solubility was measured into several solvents considered potentially eligible (either for toxicity or solubility in SC-CO₂) to be applied to the SAS process for recrystallizing active pharmaceutical ingredients. A list of every tested solvent is given in Table 2. They vary in their intrinsic properties of polarity and proticity and are classified according to their relative permittivity ε. Four solvents were selected, for which the solubility of STZ is included between 0.75 and 10% in weight concentration. Solubility lower than 0.75% w/w. is quite low for a good productivity of the process whereas solubility higher than 10% w/w. may imply drug solubilization in the supercritical phase during the SAS process. These four solvents are acetone, acetonitrile, tetrahydrofuran and acetic acid. Every other tested solvent doesn't solubilize a large enough amount of STZ to be used in this study, except for dimethyl sulfoxide and N-Methyl-2-pyrrolidone, both solubilizing STZ over 10%w/w. Logically, only polar solvents allow a good solubility for STZ, exhibiting a better affinity for aprotic solvents than for protic ones.

Solubility was obtained from calibration curves shown in Fig. 2, giving the density of the organic solution according to the concentration of STZ in it. Density measurements were performed at 293 K.

Fig. 2. Density calibration curves at 293 K for (a) acetone, (b) acetonitrile, (c) tetrahydrofuran, (d) acetic acid.

3.2. Influence of operating conditions on polymorphic form

The SAS experimental conditions performed during this work are listed in Table 3. Polymorphic form obtained from solid state NMR are also reported. ^{13}C NMR spectra are presented in Fig. 3, for powders of pure form I, pure form IV and a mixture of form I and IV.

For each of the three solvents, Acetone, Acetonitrile and Tetrahydrofuran, a dozen experiments mainly led to the formation of powders composed of a mixture of polymorphs (I and IV). Nevertheless, it is worth noting that for each solvent, pure polymorphic forms (I or IV) were obtained for given operating conditions. In addition, experiments with acetic acid led exclusively to the formation of pure polymorphic form I.

CO_2 and organic solution (OS) flow rates as well as STZ concentration in the OS were varied to identify operating conditions allowing the formation of powders that exhibit only one polymorphic form. To interpret the effect of hydrodynamics on the polymorphic nature of obtained particles, Reynolds numbers describing the flows of the organic solution jet (Re_{jet}) and of the carbon dioxide into the precipitation vessel (Re_{CO_2}) were calculated as follows:

$$Re_{jet} = \frac{\rho_{orga} u_{jet} d_{nozzle}}{\mu_{orga}} \quad (1)$$

$$Re_{\text{CO}_2} = \frac{\rho_{\text{CO}_2} u_{\text{CO}_2} d_{autoclave}}{\mu_{\text{CO}_2}} \quad (2)$$

Where ρ_{orga} and ρ_{CO_2} are measured organic solution and carbon dioxide densities, respectively, u_{jet} is the jet velocity at the exit of the injection nozzle of a diameter d_{nozzle} of 127 μm , u_{CO_2} is the CO_2 velocity throughout the crystallization vessel (considering only CO_2) of a diameter of 60 mm, μ_{orga} (measured) and μ_{CO_2} [36] are organic solution and carbon dioxide viscosities, respectively.

The Reynolds numbers associated to both flows correspond to laminar flows ($Re < 2500$) since they vary from 73 to 2157 for the organic solution flow and from 15 to 155 for the CO_2 flow. These values of Reynolds numbers correspond to different modes of jet dispersion; the highest values corresponding to atomized jet leading to more intense

mixing conditions.

Furthermore, the characteristic times associated to the different effects controlling the jet dispersion were calculated [37]. Inertial, aerodynamic and viscous effects were calculated for each presented experiment. Inertial and aerodynamic effects are preponderant since their associated characteristic times, respectively between 16 up to 508 μs and 17 up to 599 μs , are the lowest in comparison with times associated with the viscous effects (20 up to 37 ms). Inertial effects have a stabilizing effect on the jet during its dispersion while aerodynamic effects are destabilizing ones.

It is evidenced that intense mixing conditions, such as for experiments #3, #18, #31 or #41, lead to the formation of pure form I. In this case, mass transfers are enhanced, and so are the nucleation rates. Besides, less intense mixing conditions such as for experiments #11, #12, #22, #23, #34 or #38, lead to the formation of form IV.

Acetic acid used as solvent represents an interesting case, as it only allows the formation of pure form I, whatever the operating conditions. It is also the only polar protic solvent used in this study. The presence of pure form I is observed at every operating condition, at both intense and moderate mixing conditions. Further investigations are required to fully interpret this observation. Experiments #41, #42 and #43 are therefore not considered in the following interpretation.

For experiments that led to pure polymorphic form, the Re_{jet} and Re_{CO_2} are plotted in Fig. 4. Points obtained from acetic acid were removed.

It shows a clear influence of the Re_{jet} on the obtained form. Amongst the presented experimental conditions, excluding points from acetic acid, every pure powder obtained at $Re_{jet} \leq 508$ is pure form IV, while every pure powder obtained at $Re_{jet} \geq 1058$ is pure form I. A region where both pure form I and pure form IV were obtained is observed at $661 \leq Re_{jet} \leq 726$. It can be noticed that the only pure form I present in this region was obtained with a higher STZ concentration in the OS ($\beta_{OS} = 70\%$, 60% for the other ones). Furthermore, the CO_2 flow rate has no direct influence on the obtained form. Indeed, both pure form I and IV were obtained at either higher or lower Re_{CO_2} values. Therefore, the mixing is more dependent on the organic solution flow rate than on the CO_2 flow rate. Obtaining a pure form IV hence has more chance to

Fig. 3. NMR spectra for the identification and quantification of form I, form IV and a mixture of form I and IV of STZ. a lines: characteristic picks of form IV at 118.6 ppm and 120.2 ppm; b lines: characteristic picks of form I at 114.2 ppm and 115.7 ppm.

Fig. 4. Re_{jet} and Re_{CO_2} numbers of conditions that led to pure polymorphic form. Form I powders were obtained in acetone (■), acetonitrile (▲) and tetrahydrofuran (●); Form IV powders were obtained in acetone (□), acetonitrile (△) and tetrahydrofuran (○).

occur at lower Re_{jet} , independently of Re_{CO_2} .

The X_{solv/CO_2} values in which pure forms were obtained are ranged between 7.3% up to 20% for form I and 3.4% up to 11% for form IV. There is therefore no evidence that the polymorphic form of a pure

powder is directly dependent on this variable. Indeed, $X_{\text{solv}/\text{CO}_2}$ has a complex influence on the polymorphic form: as it rises, the solute solubility in the continuous fluid phase increases and, consequently, the overall supersaturation decreases and the concentration gradient between the dispersed and the continuous phases decreases. This slows down the nucleation and growth rate and thus may promote the formation of the most stable form. For example, Kordikowski et al. measured the STZ molar solubility in both pure and methanol modified CO_2 . At 10 MPa and 313 K, it rises from 8.1×10^{-9} in pure CO_2 to 1.56×10^{-5} in the modified phase containing $X_{\text{methanol}/\text{CO}_2} = 0.1412$ [19]. However, the highest values of $X_{\text{solv}/\text{CO}_2}$ are inevitably obtained at high organic solution flow rates, which promotes the formation of the less stable form due to more intense mixing conditions.

Solvent nature also has an important influence over the polymorphic form for given flow rates of both phases. Indeed, some key comparisons, for example experiments #4, #19 and #34 together, or experiments #7, #20 and #35 together, show that for a different solvent but with similar flow rates of both phases, the resulting powder is different. Indeed, in the first mentioned set, an organic solution flow rate of 1.9 mL min^{-1} and a CO_2 flow rate of 21 g min^{-1} are applied.

When acetone is used (#4), a polymorphic mixture is obtained, whereas when acetonitrile (#19) or tetrahydrofuran (#34) are used, a pure form IV powder is obtained. In the second mentioned set, the organic solution flow rate was set at 1.9 mL min^{-1} and the CO_2 flow rate was set at 10 g min^{-1} . In this case, when the organic solvent is acetone (#7), the obtained powder is 100% form IV, while a mixture of both was obtained when acetonitrile (#20) or tetrahydrofuran (#35) are used.

The initial concentration of STZ in the organic solution also has an influence on the polymorphic behavior as it has a direct connection with overall supersaturation. Experiments #18 and #19, using acetonitrile as solvent, show a shift in the polymorphic form of resulting powders from pure form IV to pure form I induced by an increased STZ concentration in the organic solution from $\beta = 0.6$ to $\beta = 0.7$. This induces a higher supersaturation, thus a faster nucleation and growth rate, at constant $X_{\text{solv}/\text{CO}_2}$. Weber Brun et al. [38] have reported a contradictory behavior in the case of caffeine crystallized with SAS. A higher proportion of the stable form (at ambient condition of pressure and temperature) has been observed at high initial concentration of solute. However, the proportion of crystalline material (crystalline versus amorphous) decreases by increasing initial concentration of

solute. In the case of a solute exhibiting more than one polymorphic form, the obtained form is not only control by the initial concentration of solute but can depend on a variety of process parameters.

Repeatability was measured for some experiments. Two reproduced experiments are given in Table 4, namely #4' and #4'' repeating experiments #4, and #12' repeating experiment #12. In every case, when either a mixture or a pure form is obtained, the repeatability is verified.

3.3. SEM observations

Crystalline powders from experiments #3, #7, #18, #19, #31, #34 and #41 (Table 3), pure in one polymorphic form, were observed with SEM. Their habits are presented in SEM photographs for forms IV and I in Fig. 5 and Fig. 6, respectively.

A wide variation of crystals habit can be shown for the form IV of STZ (Fig. 5). When reprocessed by SAS from pure acetone (#7), STZ crystals exhibit large and extremely thin plate- or leaf-like habit. The particle size distribution (PSD) shows two peaks, one around 3 μm and the other around 20 μm . This distribution is classical in the case of fragile crystals. The smaller particles are the result of either attrition during the crystallization/washing steps, leading to the formation of spherical particles (diameter under or close to 1 μm), or mechanical breaking of larger crystals, inside the reactor, during the collecting step or during the SEM sample preparation. When acetonitrile was used as a solvent (#19), crystal habit was equant. The obtained powder has a narrow PSD, at around 2 μm . Lastly, when the solvent used was tetrahydrofuran (#34), crystal habit is of a plate-like type like that of acetone. An important aggregation is however evidenced with the formation of spherical clusters. This behavior prevents attrition and breaking from occurring, the obtained powder therefore has a narrow PSD.

From these pictures, two different crystallization mechanisms have been identified:

- A nucleation and growth mechanism, leading to particles with a crystal shape, such as those obtained in acetone (Fig. 5, #7) and acetonitrile (Fig. 5, #19). This highlights a gas-like phase composed of all the 3 components in a continuous, mixed phase. Crystal growth occurs by the successive adhesion of crystal units that diffuses through the bulk. In this liquid-like behavior, the growth rate strongly depends on the probability of a crystal unit meeting a grown crystal. Reducing the crystal size can therefore be achieved by decreasing the solute concentration, for example.
- A droplet drying mechanism, leading to quasi-spherical particles composed of aggregated nanocrystals, such as those obtained in tetrahydrofuran (Fig. 5, #34). In this case, an interface still exists between the CO_2 -rich phase and the organic solution droplet, imposing the spherical shape of generated particles. Crystallization kinetics are therefore highly dependent on the double-diffusivity effect, mostly affected by the affinity between solvent and CO_2 .

STZ crystals of form I (Fig. 6) exhibit two different crystal habits, namely needle-like, and aggregated clusters of plate-like habits, corresponding to the nucleation and growth mechanism and the droplet drying mechanism, respectively. The latter is observable with all tested solvent, while being mainly observed with acetone and acetonitrile (#3 and #18, respectively, 100% of observed particles), but also visible with tetrahydrofuran (#31) and with acetic acid (#41). The nucleation and growth mechanism is only observable when tetrahydrofuran and acetic acid were used, both experimental conditions leading to needle-like crystals. This habit clearly indicates that the growth rate of one or a couple of faces has been slowed down. PSD for an observed sample with

both acetone and acetonitrile are narrow around 3 and 2 μm , respectively. However, with both tetrahydrofuran and acetic acid, the PSD is widely distributed. This is due to the combined presence of needle-like crystals and spherical clusters. The smaller particles are observed in the case of acetic acid used as a solvent.

This large habit disparity of crystal habits, for both polymorphic forms IV and I, highlights how important the solvent is for controlling crystal habit. The solvent acts as a growth inhibitor for a given set of crystal faces by adsorbing differently at the surface of every crystal face. The higher the solvent adsorption, the higher the drop of the surface free energy, for a given crystal face. Moreover, it is well established that the different surface free energy of each crystal's face is habit-controlling, and can be modified by solvent adsorption [39]. Therefore, predicting the crystal habit can be performed by predicting the surface energy as well as solvent adsorption energies thanks to molecular modelling [40]. A current work consisting in the prediction of solvent adsorption energies for STZ is ongoing to validate the method for crystallization in a supercritical medium.

4. Conclusions

The polymorphic and habit control of sulfathiazole has been studied from the supercritical antisolvent process and with different organic solvents. At moderate mixing conditions and for low supersaturation values, the form IV is obtained, whilst at intense mixing conditions, fast nucleation kinetics lead to formation of form I. Furthermore, crystal habit can be severely influenced by the solvent. Indeed, depending on the solvent nature, polymorphic form IV crystals of sulfathiazole can exhibit a thin plate-like habit or an equant habit. The same behavior occurs for the polymorphic form I crystals of sulfathiazole, exhibiting either a plate-like habit or a needle-like habit. More importantly, two crystallization mechanisms have been identified and are affected by the nature of solvent. These two mechanisms are liquid-like nucleation and growth mechanism and droplet drying mechanism, and depend on hydrodynamic conditions as well as on the affinity between organic solvent and CO_2 . These two behaviors further point out how important and complex the choice of a solvent is for particle generation with the supercritical anti-solvent process.

The strong dependence of crystal habit on the solvent used, in the case of nucleation and growth mechanism, can be imputed to the solvent's ability (or inability) to perform strong intermolecular interactions with a given set of crystal faces. These intermolecular interactions can be regarded as solvent molecules adsorbed at the surface of a crystal, which may be the cause of the crystal habit changes. Adsorption energies can be calculated through molecular modelling to predict and control the crystal habit, for example in a drug producing perspective.
