In the present study, we examined the UV excitations of a newly introduced molecular set, Halons-9, composed of nine gaseous halon molecules. The performance of the density functional-based multi-reference configuration interaction method (DFT/MRCI) and time-dependent density functional theory with CAM-B3LYP functional (TD-CAM-B3LYP) in the computation of singlet and triplet excited states of this set was evaluated against coupled-cluster with singles and doubles (CCSD). Excited states up to the corresponding ionization limits, including both localized and delocalized excitations, have been benchmarked. TD-CAM-B3LYP significantly underestimates excitation energies of the higher mixed valence-Rydberg and Rydberg states, with computed mean absolute deviations from the EOM-CCSD results 1.06 and 0.76 eV, respectively. DFT/MRCI gives a significantly better description of higher excited states, albeit still poor, compared to the TD-CAM-B3LYP. The mean absolute deviations of mixed valence-Rydberg and Rydberg states from the reference EOM-CCSD values are 0.66 and 0.47 eV, respectively. The performance of DFT/MRCI for description of strongly correlated states with valence-Rydberg mixing is still not satisfactory enough. On the other hand, oscillator strengths of most of singlet states obtained with both methods are close to the EOM-CCSD values. The largest deviations, occurring in the case of several high-lying multiconfigurational states, are of an order of magnitude.

Keywords: halons, excited states, benchmarking, DFT/MRCI, TD-DFT

I. INTRODUCTION

One of the main challenges in quantum chemistry is the reliable prediction of excited-state properties. Numerous theoretical methods for computation of excited states have been introduced and assessed, among them several popular single-reference methods (e.g. the linear-response time-dependent density functional theory (TD-DFT)^{1,2} and coupled-cluster-based methods), as well as multi-reference methods (e.g. the complete active space second-order perturbation theory (CASPT2)³ and the multi-reference configuration interaction (MRCI)⁴ method). However, selecting an appropriate electronic structure method for excited state computation in a particular case, in terms of accuracy and computational cost, is not a straightforward problem.

A number of computational studies have been devoted to performance evaluation of different quantum chemistry methods for prediction of various molecular properties on different molecular sets.⁵⁻¹¹ Since the focus of this study is on excited states, we here mention few well-established molecular sets, which stand out among numerous sets used in methods assessments. The molecular set by Thiel and his co-workers⁵, an assembly of 28 small representative organic molecules, is one of the most widely used molecular sets. It has been employed for evaluation of excited states of several multi- and single-reference methods.⁵⁻⁸ Furthermore, Grimme and his co-workers introduced several molecular sets⁹⁻¹². The first of them⁹ comprises 14 middle-sized to large molecules, including organic and inorganic molecules, where the studied excited states included the lowest-lying localized and Rydberg states. The molecular set composed of 14 small- to medium-sized molecules, introduced by Leang et al., was used for benchmarking of TD-DFT with various density functionals¹³. Winter et al. introduced a molecular set of 66 organic molecules, including porphine derivatives, polycyclic aromatic hydrocarbons, heterocyclic organic compounds and aromatic alcohols, and assessed several single-reference methods for the excited state computations¹⁴.

By inspecting these and other prominent molecular sets, we noticed that a large field of halo-organic compounds remained not properly covered by any of them. This motivated us to introduce a new molecular set, Halons-9, composed of nine halon molecules: bromomethane (CH_3Br), dichlorofluoromethane (CHCl_2F), bromodifluoromethane (CHBrF_2), bromochlorodifluoro-methane (CBrClF_2), dichlorodifluoromethane (CCl_2F_2), bromotrifluoromethane (CBrF_3), tetrafluoromethane (CF_4), 1,2-dichlorotetrafluoroethane ($\text{C}_2\text{Cl}_2\text{F}_4$),

and hexafluoroethane (C_2F_6). Among all halon molecules, we have chosen to investigate the excited states of only those which are gaseous under standard conditions of temperature and pressure, primarily because of their importance in atmospheric chemistry. The structures of the studied molecules, alongside their IUPAC names and names according to the special halons’ naming convention are shown in Figure 1. To our knowledge, none of the existing molecular sets included any of these molecules. Apart from CH_3Br , whose low-lying excited states are examined in several studies^{15–17}, excited states of the other molecules in the set have not yet been studied computationally. Nevertheless, there are numerous experimental studies of the UV spectra of halons (for CH_3Br ref.¹⁸ and the references cited herein; for $CBrF_3$ ref.^{19–21} and the references cited herein; for CF_4 ref.^{22,23} ; for $CHCl_2F$ ref.²⁴ ; for $CHBrF_2$ ref.²¹ ; for $CBrClF_2$ ref.^{21,25,26} ; for CCl_2F_2 ref.^{24,27} ; for C_2F_6 ref.²⁸ ; for $C_2Cl_2F_4$ ref.²⁹).

This omission may impact the evaluation of computational methods and properties by introducing a negative bias against halogen compounds. We particularly felt that in recent simulations of halo-compounds of atmospheric interest^{30–34}, where we could not count on performance evaluation for any of the molecules of interest. Our aim in this study is to start to fill this knowledge gap, first, by proposing a clear set of molecules to be tested; and second, by evaluating them using few popular methods. As a first study, we limited ourselves to the investigation of spin-free vertical excitation energies for the whole series. Important topics as adiabatic excitation energies and spin-orbit coupling will be left for further studies. We probed the performance of two DFT-based quantum chemical methods against equation of motion CCSD (EOM-CCSD)^{35–38} in the computations of excited states of these systems.

We focus on performance of density functional theory-based multi-reference configuration interaction method (DFT/MRCI)³⁹ and TD-DFT in combination with CAM-B3LYP functional^{40,41} in description of excited states of halons. The 240 excited states included in our study comprise a small number of valence excited states in low-energy regions and numerous highly-correlated Rydberg and mixed valence-Rydberg states in high-energy regions converging to the ionization limits.

TD-DFT stands out among other computational methods as one of the most popular due to its good compromise between accuracy and computational cost. Several different flavors of density functionals have been developed, and their performance has been benchmarked

against high-level ab initio or experimental data so far, probing their performance for a range of excited states, from localized to delocalized ones.^{42–48} One of the main drawbacks of TD-DFT is the description of systems with pronounced multi-reference character of ground state. Moreover, within the usual linear-response and adiabatic approximations, TD-DFT is incapable of reproducing doubly-excited states⁴⁹.

DFT/MRCI overcomes a large number of shortcomings of TD-DFT, because of its multi-reference character. It is better suited to treat highly-correlated systems, and to capture the excited states of double-excited character. The DFT/MRCI method has been tested for a number of organic molecules^{39,44,50–52} and transition metal complexes⁵³, applied for simulation of UV/vis spectra (e.g. Ref.^{54–56}), and recently assessed for the computation of spin-orbit coupling in organic molecules⁵⁷. It has been shown that it is able to reproduce excitation energies with errors within few tenths of an eV. However, most of the available benchmark studies of excited states with DFT/MRCI are usually focused on valence excited states of $n\pi^*$ or $\pi\pi^*$ character, and do not include higher states characterized by σ bond excitations, valence-Rydberg mixing, and Rydberg states.

EOM-CCSD computations of excited states are used as the reference data for the comparison with DFT/MRCI and TD-DFT results. Although it is one of the most reliable methods available for routine excited state calculations, we should mention that, just like TD-DFT, it is not able to describe multi-reference and double excitations. Therefore, concerning these properties, we should take DFT/MRCI as the reference.

II. METHODS AND COMPUTATIONAL DETAILS

The ground state molecular structures of the nine molecules in the Halons-9 molecular set have been optimized using Møller-Plesset perturbation theory up to the second order (MP2)^{58–61} with def2-TZVPP basis set⁶² without symmetry constraints. First ionization potentials of the studied molecules are computed at their optimized structures using coupled cluster with singles and doubles (CCSD) method^{63–66} with the triple-zeta def2-TZVPP basis set, as the difference between the ground state energy of the N and the $N - 1$ electron systems. Cartesian coordinates for the optimized structures are given in the Supporting Information (Tables I-IX) and vertical ionization potentials (IPs) are given in Table I. Vertical

excitation energies of singlet and triplet excited states up to around the ionization limits are computed at the optimized structures at three different levels of theory - EOM-CCSD³⁵⁻³⁸, DFT/MRCI³⁹, and linear response TD-DFT. We tested the influence of size of the basis set on excited state energies of CF₄ by comparing their values obtained with the def2-TZVPP and quadruple-zeta def2-QZVPP⁶² bases (see Table X in the Supporting Information). The def2-QZVPP basis set decreases the vertical excitation energies of CF₄ molecule for ≈ 0.3 eV in average. Since we are primarily interested to compare the performances of applied methods, we decided to use smaller def2-TZVPP set in all computations.

Since excited states with pure Rydberg or mixed valence-Rydberg character are expected to occur among the computed excited states, TD-DFT computations are performed employing range-separated (rs) hybrid Coulomb attenuated method CAM-B3LYP functional^{40,41}. As it is well-known⁶⁷ generalized gradient approximation (GGA) and hybrid exchange-correlation functionals usually describe accurately local excitations, with an accuracy of few tenths of an eV. However, they significantly underestimate excitation energies of non-local states, such as Rydberg or charge-transfer excitations⁶⁸, with the typical errors of order of an eV. The origin of this problem is already very well-known - it lies in an incorrect description of long-range exchange functionals with GGA and hybrid functionals⁶⁹⁻⁷¹. This problem can be overcome using range-separated functionals, which describe short- and long-range exchange functionals by different terms. One of the most widely used rs functionals, CAM-B3LYP, comprises 0.19 Hartree-Fock(HF)-like and 0.81 Becke 1988 (B88) GGA exchange at short range; the long-range region is represented by 0.65 HF-like plus 0.35 B88 exchange; and the transition between short- and long-range regions is modulated by an error function with parameter $0.33 a_0^{-1}$.⁴⁰ Assessed for the computation of excitation energies of Rydberg and charge transfer states, CAM-B3LYP generally shows good performance.^{72,73}

To analyze the delocalization of the excited states obtained on TD-CAM-B3LYP level, we employ the Λ diagnostic, introduced by Peach et al.⁷⁴, as a method to quantify the degree of delocalization of states within TD-DFT method. The Λ values are computed as sums of spatial overlaps between all occupied and virtual orbital pairs involved in TD-DFT excitations, weighted by their contributions to the specific excited state. These contributions are obtained by solving Casida's equations⁷⁴. The Λ value is a dimensionless number which takes value between 0 and 1; small Λ values signify excitations with strong delocalized characters, whereas large values signify local excitations. All presented TD-DFT computations

were performed with GAMESS-US code^{75,76}.

The basic idea of the combined density functional theory/multi-reference configuration interaction (DFT/MRCI) method is to perform DFT computations of a closed-shell reference ground state, and to use the obtained one-particle Kohn-Sham (KS) orbitals as a basis to subsequently build configuration state functions (CSFs) with short MRCI expansions.³⁹

The Hamiltonian matrix elements computed between the CSFs with the same space and same spin parts (diagonal elements) are the most important, because CI-matrix is usually diagonal-dominant. They account for most of dynamic electronic correlation included via DFT. On the other hand, the off-diagonal Hamiltonian matrix elements are computed between CSFs with same space but different spin parts or between CSFs with one-electron or two-electron differences in space parts. In DFT/MRCI off-diagonal matrix elements are scaled using exponential damping function, which depends on the energy difference between diagonal elements of two CSFs. This scaling is introduced to avoid large extent of double counting of electron correlation which is already included via diagonal terms. It also ensures efficient selection of energetically close CSFs, whose interaction gives rise to non-dynamic correlation effects which are not taken into account within DFT. A few semi-empirical screening parameters are employed in the DFT/MRCI Hamiltonian, including parameters used for fitting the exponential damping function for scaling procedure and parameters used for screening of two-electron integrals in diagonal matrix elements.

In our DFT/MRCI computations, the reference configurations were initially generated by single and double excitations of ten active electrons within the active space composed of ten orbitals. We discard the configurations with energies above 1 Hartree. The number of created configurations spans from 946 in the case of CF₄ molecule to 10139 in the case of C₂Cl₂F₄ molecule. We employ the original sets of five empirical parameters for singlet and triplet excited states for the DFT/MRCI Hamiltonian^{39,77}, which are available in combination with the BH-LYP functional⁷⁸.

The initial DFT calculations are performed with TURBOMOLE program⁷⁹, and the subsequent MRCI computations are done with the MRCI code developed by Grimme and Waletzke³⁹ and recently updated by Lyskov and co-workers⁸⁰. The two-electron integrals in DFT/MRCI computations were approximated using the resolution-of-the-identity approximation with auxiliary basis set⁸¹ from the TURBOMOLE library.

The spin-restricted EOM-CCSD computations and the MP2 geometry optimizations are

performed with Gaussian 09 program⁸².

III. RESULTS AND DISCUSSION

A. Vertical excitations

Computed vertical excitation energies, state assignments, and their Λ values are compiled in Table II for the singlet and in Table III for the triplet excited states. Oscillator strengths for the singlet transitions are given as well. For the sake of brevity, we only show the singlet excited states with oscillator strengths larger than 0.001 and only the first 5 triplet excited states for each molecule. Complete Tables including all computed excited states are given in the Supporting Information (Table XI and Table XII).

The assignment of the excited states computed with the applied methods is done by analyzing the nature of orbitals involved in the main excitations contributing to each particular state. The states computed with different methods were correlated according to their determined types and weights of main configurations. In the case of several high-lying multi-configurational states, correlation of the excited states computed with EOM-CCSD and the DFT-based methods according to these criteria is non-trivial due to a pronounced configuration mixing within EOM-CCSD, which is not particularly well reproduced with DFT/MRCI and TD-CAM-B3LYP methods. In these cases, the comparison of the oscillator strength values and the symmetry representation of the states were also helpful for the assignment. Weights of the main configurations obtained with EOM-CCSD are given in the tables in the cases where it was possible to determine them. For numerous states, however, arising from the excitations between mixed orbitals (represented as linear combinations of different orbital types, for instance $n\sigma^*$ and Rydberg orbitals), the configuration weights are not computed.

According to the DFT/MRCI results, all computed states are single-reference and singly-excited, with negligible contributions of doubly-excited configurations (less than 5 %). This implies that all states obtained with DFT/MRCI could in principle be also computed with EOM-CCSD and TD-DFT methods, which are unsuited to capture states with predominantly multi-reference and doubly-excited character.

Based on the assignment, the benchmark set of 240 excited states was split into 64 localized

valence states, 91 Rydberg states, and 85 states of mixed valence-Rydberg character; and into 110 singlet and 130 triplet states. The correlation graphs between the TD-CAM-B3LYP and DFT/MRCI vertical excitation energies with the corresponding EOM-CCSD values are shown in Figure 2, separately for singlet and triplet excited states. Some of the features of the computed states are noticeable from first sight. Both DFT/MRCI and TD-CAM-B3LYP underestimate excitation energies of all computed states. DFT/MRCI excitation energies lie in between EOM-CCSD and TD-CAM-B3LYP values, significantly closer to the EOM-CCSD values. The standard deviation of DFT/MRCI vertical excitation energies from the corresponding EOM-CCSD values is 0.49 for singlet and 0.51 for triplet states, whereas for TD-CAM-B3LYP these values are 0.72 and 0.79 respectively. Both methods describe slightly better singlet than triplet states.

For most of molecules, several pure valence excited singlet and triplet states occur in the low energy region. They are usually of $n\sigma^*$ type, but there are also several states of $\sigma\sigma^*$ or mixed $n\sigma^* - \sigma\sigma^*$ type. These states emerge upon excitations from the highest HOMO orbitals of non-bonding or σ type to the lowest-lying LUMO and LUMO+1 orbitals. In these cases, the lowest-lying LUMO orbitals are anti-bonding $\sigma^*(\text{C-Br})$ or $\sigma^*(\text{C-Cl})$. Exceptions to this behavior are CF_4 and C_2F_6 molecules, where the LUMO orbitals are Rydberg ones. This induces the lowest-lying excited states of CF_4 and C_2F_6 to be Rydberg. Since the energies of the $\sigma^*(\text{C-F})$ orbitals are higher than the energies of the Rydberg orbitals, states of pure $n\sigma^*$ and $\sigma\sigma^*$ character do not occur, whereas states with mixed Rydberg and $n\sigma^*$ configurations occur only in the upper parts of their spectra, contrary to the other molecules in the set (Table XI and Table XII, Supporting Information). In all cases, the medium part of the excited state spectrum is characterized by numerous multiconfigurational excited states featured by considerable valence-Rydberg mixing.

The highest excited states are mostly purely Rydberg states. In several cases, few delocalized states of $n\sigma^*$ character appear in the upper part of the spectrum. These states arise from excitations from the compact non-bonding orbitals of fluorine to the $\sigma^*(\text{C-Br})$ or $\sigma^*(\text{C-Cl})$ orbitals, which have a small spatial overlap.

This pattern occurring in the excited states spectrum could be explained by energy ordering of molecular orbitals, common to all molecules, $\sigma(\text{C-F}) < \sigma(\text{C-Cl}) < \sigma(\text{C-Br}) < n(\text{F}) < n(\text{Cl}) < n(\text{Br}) < \sigma^*(\text{C-Br}) < \sigma^*(\text{C-Cl}) < \text{Rydberg} < \sigma(\text{C-F})$. The compositions of the lowest Rydberg orbitals varies, but in most of cases they are represented as linear combinations

of several atomic orbitals rather than as a pure one. Based on this ordering of orbitals, it could be predicted that in the molecules containing C-Cl and C-Br bonds, the lowest-lying excited states would be of $n\sigma^*$ character, while in molecules containing only C-F and C-C bonds, the lowest lying excited states would be Rydberg states.

B. TD-DFT results

A summary of statistical evaluation, including mean errors (ME), mean absolute errors (MAE), standard deviations (SD), maximum and minimum errors for TD-CAM-B3LYP and DFT/MRCI results with respect to EOM-CCSD results is given in Table IV and Figure 3, separately for valence, mixed valence-Rydberg, Rydberg, and all studies states. Comparing TD-CAM-B3LYP vertical excitation energies with the corresponding EOM-CCSD values, it could be noticed that among all the excited states, valence states are described the best on TD-CAM-B3LYP level. Their MAE from the EOM-CCSD results is 0.58 eV. Analyzing the valence state compositions, we find that the lowest-lying valence states, arising upon excitations from the highest occupied non-bonding orbitals to the LUMO orbital, are described fairly well. The MAE of their vertical excitation energies from EOM-CCSD values is 0.38 eV for singlet (18 states) and 0.48 eV for triplet (20) excited states. These states are mostly $n\sigma^*$ states represented mainly by a single configuration (Table II, Table III, and Table XI, Table XII in the Supporting Information).

The description of the higher excited states deteriorates in the upper region of the spectrum. In several cases, the ordering of the states obtained with TD-CAM-B3LYP differs from that obtained with EOM-CCSD. The excitation energies of higher valence, mixed valence-Rydberg, and Rydberg states are severely underestimated. The high-energy $n\sigma^*$ valence excited states occurring in CCl_2F_2 , CBrClF_2 , and $\text{C}_2\text{Cl}_2\text{F}_4$ are placed significantly lower compared to the EOM-CCSD results (their maximum deviation is 1.1 eV). The most dominant configurations contributing to these states involve transitions from the highest HOMO orbitals to LUMO+1 orbitals, which is the $\sigma^*(\text{C-Cl})$ orbital (in the cases of CCl_2F_2 and $\text{C}_2\text{Cl}_2\text{F}_4$ this is the higher $\sigma^*(\text{C-Cl})$ orbital).

The excitation energies of the pure Rydberg states are also systematically underestimated compared to the EOM-CCSD results, with MAE of 0.76 eV and maximum error of 1.20 eV. We employ the Λ diagnostic to analyze the correlation between the degree of delocalization

of the states with dominant Rydberg character and the errors of their excitation energies. The obtained Λ values of the studied Rydberg states are in the range between 0.2 and 0.65 (Figure 1 in the Supporting Information). Analyzing the deviations of TD-CAM-B3LYP excitation energies of Rydberg states against the corresponding Λ values for Rydberg excited states, it could be noticed that in the cases of three molecules (C_2F_6 , $CBrF_3$, $C_2Cl_2F_4$) there is no correlation between excitation energy errors and Λ values. In the majority of cases, however, the deviations of the excitation energies are larger in the cases of more delocalized states, which are characterized by smaller Λ values. The excitation energy errors for most of molecules slowly reduce upon increasing of Λ values (Figure 1 and Table XI in the Supporting Information), but they still remain large (close to 1 eV) even for Rydberg states with relatively large Λ values.

A tendency of improvement of the excitation energies for the states with larger Λ values could indicate that CAM-B3LYP functional does not describe correctly the long-range behavior of the exchange functional and that additional asymptotic correction of the functional is necessary. This behavior of CAM-B3LYP functional has already been observed before in several different benchmark studies (e.g. Ref.⁷⁴). However, in the case of halons, the MAE of the Rydberg states' excitation energies (0.76 eV) is close to the one of the valence states (0.56 eV), and it is smaller than the corresponding value of the mixed valence-Rydberg states (1.06 eV). This indicates that the eventual incorrect description of the long-range behavior of the exchange functional with TD-CAM-B3LYP is not the most important source of the errors of excitation energies of halons.

The excitation energies of the states with mixed valence-Rydberg character are also severely underestimated on TD-CAM-B3LYP level. The MAE of the excitation energies compared to EOM-CCSD results is 1.06 eV, whereas the maximum deviation is 1.33 eV. Such large excitation energy errors are due to underestimation of the excitation energies of Rydberg orbitals, but also seem to be correlated to the pronounced multiconfigurational character of these states.

The Λ values of the states with mixed valence-Rydberg character are spread in similar region as pure Rydberg states (Figure 1, Supporting Information), from 0.2 to 0.7, but their mean Λ value (0.73) is larger than the mean Λ value for pure Rydberg states (0.65). Also, their mean deviation from the EOM-CCSD results (1.06 eV) is larger than one for Rydberg states (0.76 eV). The low-lying valence states have Λ values concentrated in the region from 0.55

to 0.65 (Figure 1, Supporting Information).

One of the interesting features occurring in the case of CCl_2F_2 and CBrF_3 molecules are the several $n\sigma^*$ excited states arising from excitation from non-bonding orbital of fluorine to antibonding $\sigma^*(\text{C-Cl})$ or $\sigma^*(\text{C-Br})$ orbitals, which could be classified as delocalized. These states are featured by very small Λ values, since the overlaps between localized non-bonding fluorine orbitals and antibonding σ^* orbitals are small in these molecules. According to EOM-CCSD results, these states occur in the highest part of the spectrum, above Rydberg states. TD-CAM-B3LYP underestimates significantly the excitation energies of these states.

TD-CAM-B3LYP performs the best in the case of the excited states of CH_3Br molecule (MAE is 0.65 eV), whereas it gives the largest errors for the excited states of CF_4 (1.03 eV) and C_2F_6 (0.93 eV), which are mainly Rydberg states.

Considering all states, TD-CAM-B3LYP systematically underestimates the excitation energies in the Halons-9 set, with a MAE of 0.82 eV (Table IV). This error is astonishingly large given the usual 0.3 eV MAE usually observed in benchmarks based on organic molecular sets,¹³ which are biased towards low-lying $n\pi^*$ and $\pi\pi^*$ states. This deterioration of the TD-DFT energies for high excitations was recognized long ago by Casida et al.⁶⁸, who traced it back to a wrong asymptotic behaviour of the exchange-correlation (XC) potential. Since then, diverse schemes have been proposed to fix the asymptotic behavior,^{68,83,84} although none of them has yet been adopted as standard in TD-DFT calculations. One of the features of this problem with the XC potential is the strong underestimation of $-E_{HOMO}$ (the negative of the HOMO energy), lying much lower than the true IP; with a consequent collapse of the higher excited states in the region between $-E_{HOMO}$ and the IP.⁴⁹ It goes beyond the scope of this work to attempt to correct this feature here, as our focus is at the performance of standards methods. However, given the strong deviation between $-E_{HOMO}$ and the IP at CAM-B3LYP level (see Table I), we note that an adequate treatment of the XC potential may help to improve the TD-DFT description of the excited state of halons.

Finally, the obtained oscillator strengths agree well with the EOM-CCSD values. The largest discrepancies are found in the cases of several multiconfigurational states, which are poorly described with TD-CAM-B3LYP.

C. DFT/MRCI results

The DFT/MRCI excitation energies for all studied states are also underestimated compared to the EOM-CCSD values, but they provide much better description of the excited states; the DFT/MRCI excitation energies lie much closer to the EOM-CCSD values. The ordering of the excited states according to DFT/MRCI coincides with the one predicted by EOM-CCSD.

Similarly as in the case of TD-CAM-B3LYP, the description of the lowest-lying valence states, which arise upon excitations from the several highest occupied orbitals to the LUMO orbital, is fairly good. However, the description of the higher excited states deteriorates. The deviations of the excitation energies from the corresponding EOM-CCSD values are larger for the higher valence, Rydberg, and mixed valence-Rydberg states. The largest deviations occur in the case of the higher valence states, where the maximum deviation from the EOM-CCSD results is 1.02 eV (Table IV, Figure 3). These states mainly arise due to excitations to LUMO+1 orbitals. The MAE of all valence states (including those formed by excitations to LUMO and to LUMO+1 orbitals) is 0.44 eV, reflecting an overall satisfying performance of DFT/MRCI for these states.

The medium and upper parts of the excited state spectra of halons are mainly featured by states with strong valence-Rydberg mixing. As a CI-based method, it is expected that DFT/MRCI should be flexible enough to treat properly these states. In principle, the DFT/MRCI description of these states is more reliable compared to TD-CAM-B3LYP, but the obtained deviations from EOM-CCSD are still significant; the MAE of the states with mixed valence-Rydberg character is 0.66 eV and their maximum error is 0.80 eV. The description of Rydberg states, on the other hand, is significantly improved compared to TD-CAM-B3LYP results; the MAE of the Rydberg states is 0.47 eV and the maximum error is 0.80 eV. Insufficiently good performances of DFT/MRCI in the cases of multiconfigurational highly-correlated excited states of several systems have already been noted before.^{53,80}

DFT/MRCI describes slightly better singlet than triplet excited states. The mean average error of the triplet states (0.53 eV) is a little bit larger compared to the error of the singlet states (0.47 eV). The trend of inferior description of triplet states, common to all DFT-based methods, has already been noticed in the case of some other benchmarking sets^{44,77}.

DFT/MRCI describes very well excited states of CF₄, C₂F₆, CF₃Br, and CH₃Br molecules,

whereas the largest deviations are found in the cases of CCl_2F_2 , $\text{C}_2\text{Cl}_2\text{F}_4$, and CBrClF_2 molecules. The bad performance in these cases is due to occurrence of the highly correlated multiconfigurational valence and valence-Rydberg states, for which the performance of DFT/MRCI is not good enough. Globally, considering all states the MAE is 0.53 eV.

Most of the computed DFT/MRCI oscillator strengths are in the range of the corresponding EOM-CCSD values. Only in a number of high-lying Rydberg and valence-Rydberg states with strong configuration mixing, which are not described very well with DFT/MRCI, there are sometimes discrepancies between DFT/MRCI and EOM-CCSD oscillator strengths.

In the last several years a lot of effort is put into development of a new method which unites advantages of multireference methods and DFT, the time-dependent multiconfigurational short-range density functional theory (TD-MC-srDFT) method⁸⁵. It consists in combining a long-range multi-configuration self-consistent field (MCSCF) treatment with an adiabatic short-range density-functional (DFT) description extended for computation of excited states in time-dependent regime. Benchmarked on a set of small organic molecules⁸⁶ and nucleobases⁸⁷, the TD-MC-srDFT method in the CAS-srPBE variant generally showed good performance. It is suitable for computation of doubly-excited states and excited states in molecules with multireference ground-state functions. However, the TD-MC-srDFT method is not reliable for description of states which display Rydberg-valence mixing^{86,87}. In their cases large errors of excitation energies are observed, and it is found that they are dependent on a chosen value of range-separation parameter^{86,87}. However, it is expected that different variants of TD-MX-srDFT method obtained combining other functionals and multireference methods, which are not tested yet, might provide better results for mixed valence-Rydberg states.

D. Comparison with **the** experimental data

The computed vertical excitation energies and the positions of band peaks of available experimental UV photoabsorption spectra are compiled in Table V. However, comparison of the computed excitation energies with the peak positions is problematic due to influences of spin-orbit and **adiabatic effects** which were not taken into account in computations of excitation energies. It is expected that spin-orbit coupling would be particularly intensive in the case of molecules which contain bromine, which is a relatively heavy element.

Man et al.¹⁹ computed absorption spectrum of bromomethane using time-dependent approach to resonance Raman scattering. They deconvoluted the A-band in gas-phase absorption spectra into three transitions: 3Q_1 at 45260 cm^{-1} (5.61 eV), 3Q_0 at 48272 cm^{-1} (5.98 eV), and 1Q_1 at 51372 cm^{-1} (6.37 eV). The positions of 3Q_0 and 1Q_1 bands are close to the values of EOM-CCSD excitation energies of the first triplet (6.01 eV) and singlet (6.64 eV) states, respectively (Table V).

In the cases of other molecules the recorded UV spectra are not resolved into spin components. In several cases the positions of band peaks are closer to S_1 and in some cases to T_1 excitation energies. In the cases of highly symmetric molecules (CF_4 , C_2F_6 , CCl_2F_2 , CBrF_3 , CH_3Br) with doubly-degenerate S_1 and T_1 states, comparison **the** reference EOM-CCSD results with the experimental ones is even more difficult, because of vibronic interactions which influence the excitation energies of these states. For these reasons, we cannot draw any conclusion about validity of the reference EOM-CCSD method. A more comprehensive study of excited states with inclusion of spin-orbit and adiabatic effects is necessary in order to compare ab initio and experimental data.

IV. CONCLUSIONS

Given the complete lack of excited state information about halo-organic compounds in excited state benchmarks, we have introduced a new molecular set tailored for evaluation of molecular properties of such systems. The Halons-9 set is composed of nine small gaseous halons, including F, Cl, and Br elements. Vertical excitation energies were assessed with two DFT-based methods, TD-DFT with CAM-B3LYP functional and DFT/MRCI methods, taking CCSD as the reference method.

The present benchmark shows that the evaluated methods only provide semi-quantitative results, with errors in the order of several tenths of an eV. Overall, we observed a superior performance of multi-reference DFT/MRCI method in the calculation of the excited states of halons (MAE is 0.53 eV), compared to TD-CAM-B3LYP method (MAE is 0.82 eV) (Table IV, Figure 3).

TD-CAM-B3LYP method performs the best for the lowest-lying valence states represented mainly by single configurations (MAE is 0.56 eV). In the case of higher valence states, states

with pronounced valence-Rydberg mixing, and Rydberg states, TD-CAM-B3LYP vertical excitation energies are significantly underestimated compared to EOM-CCSD values. The description of the mixed valence-Rydberg states with TD-CAM-B3LYP is the most challenging; the MAE of the mixed valence-Rydberg states is the largest (1.06 eV), whereas the MAE of the pure Rydberg states (0.76 eV) is considerably larger than the one of the valence states (0.56 eV).

On the other hand, DFT/MRCI method performs reasonably well for most of the studied states. It gives much more reliable description of states with pronounced multiconfigurational character, which appear in the middle and upper parts of the spectrum, compared to TD-CAM-B3LYP. The largest deviations from the EOM-CCSD values are observed in the case of higher-lying multiconfigurational mixed valence-Rydberg states.

Contrary to expectations based on previous numerous benchmarking studies, where valence excited states are usually described with errors around 0.2 to 0.3 eV with TD-DFT or DFT/MRCI, the valence excited states of Halons-9 molecular set are described only semi-quantitatively with both methods (the MAE of valence states' excitation energies obtained with TD-CAM-B3LYP and DFT/MRCI are 0.58 and 0.44 eV, respectively). The reason for this is in the fact that most of benchmark studies focus on organic molecules with low-lying $n\pi^*$ or $\pi\pi^*$ excited states. By construction, the excited states in the Halons-9 molecular set ($n\sigma^*$, $\sigma\sigma^*$, n-Rydbergs, and mixed valence-Rydbergs) are much higher. In this spectral region, the effects of wrong asymptotic behaviour of the XC potential are much more pronounced, leading to a deterioration of the results.

Oscillator strengths for most of the transitions are described satisfactorily with both methods. The exceptions are strongly-correlated multiconfigurational states, where, in the cases of several states, oscillator strengths strongly deviate from the EOM-CCSD values.

All molecules in the Halons-9 set are featured by electronic transitions in far- and extreme UV-region, implying that these transitions cannot be photoactivated close to the Earth's surface, although they may play a role in the photochemistry of the high atmosphere.

We were not able to evaluate the validity of the EOM-CCSD method, which was used as the reference, because of the UV excitation of most of molecules in the Halons-9 set should be strongly affected by spin-orbit couplings. For this reason, we limited our analysis to computational methods. The effect of spin-orbit coupling and adiabatic effects on excited state of Halons-9 set will be investigated in our future work.

V. ACKNOWLEDGMENTS

This Project was funded by the Deanship of Scientific Research (DSR) King Abdulaziz University, Jeddah, under grant no.43-130-35-RG. The authors, therefore, acknowledge with thanks DSR support for Scientific Research. Also, the authors appreciate the kind cooperation provided by the Deanship of Scientific Research (DSR), King Abdulaziz University. MB and LS thank the support of the A*MIDEX grant (no. ANR-11-IDEX-0001-02) and of the project Equip@Meso (ANR-10-EQPX-29-01), both funded by the French Government "Investissements d'Avenir" program. They are also in debt to Prof. Christel Marian, who kindly provided the latest version of the DFT/MRCI program. LS also acknowledges Miquel Huix-Rottlant for help with the GAMESS code.

UV Excitations of Halons

FIG. 1. The molecular structures of the nine studied halon molecules (Halons-9 molecular set).

UV Excitations of Halons

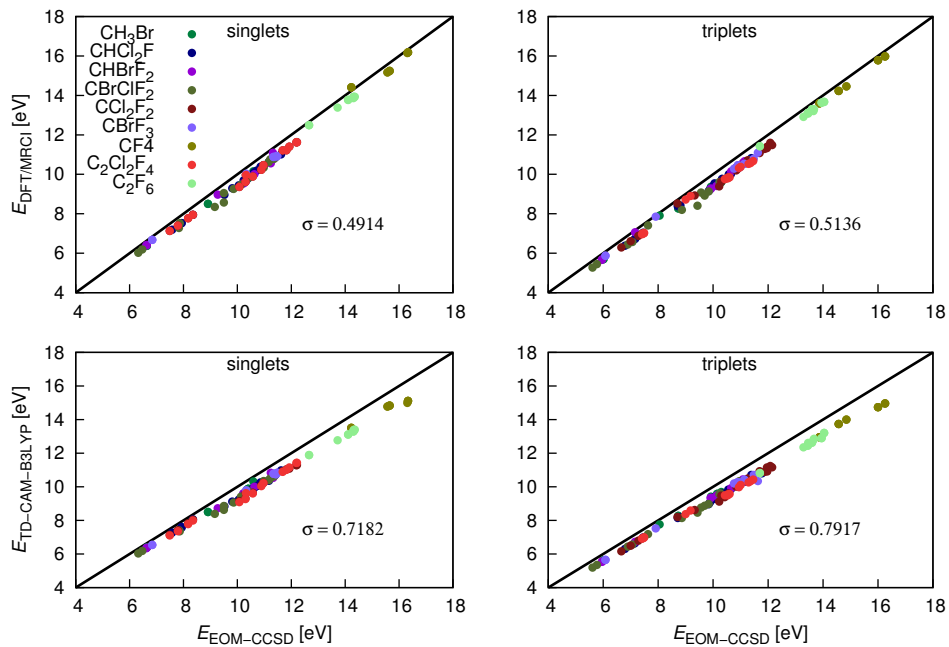

FIG. 2. The correlation diagrams of vertical excitation energies (in eV) for the Halons-9 molecular set obtained with DFT/MRCI and TD-CAM-B3LYP methods, with vertical excitation energies obtained with EOM-CCSD method.

FIG. 3. The mean absolute errors of the vertical excitation energies from the corresponding EOM-CCSD values (in eV) of valence, mixed valence-Rydberg, Rydberg, and all studied states of the Halons-9 molecular set obtained with TD-CAM-B3LYP and DFT/MRCI.

TABLE I. Vertical ionization potentials (IP in eV) computed on CCSD/def2-TZVPP level at the MP2/def2-TZVPP optimized geometries and negative values of HOMO energies ($-E_{HOMO}$ in eV) obtained with CAM-B3LYP/def2-TZVPP of the Halons-9 molecular set.

Molecules	IP (eV)	$-E_{HOMO}$ (eV)
CH ₃ Br	10.54	9.29
CHCl ₂ F	11.86	10.54
CHBrF ₂	11.44	10.24
CBrClF ₂	11.48	10.29
CCl ₂ F ₂	12.21	10.87
CBrF ₃	11.68	8.70
CF ₄	16.60	14.24
C ₂ Cl ₂ F ₄	12.60	11.24
C ₂ F ₆	14.67	12.99

TABLE II: Computed vertical excitation energies (eV), oscillator strengths, assignment of the states and Λ values for the Halons-9 molecular set.

TABLE IV. Mean error (ME), mean absolute error (MAE), standard deviation (SD) and maximum and minimum deviations (in eV) of the DFT/MRCI and TD-CAM-B3LYP excitation energies from EOM-CCSD results for the Halons-9 molecular set.

		TD-CAM-B3LYP	DFT-MRCI
Valence (64 states)	ME	-0.58	-0.44
	MAE	0.58	0.44
	SD	0.63	0.48
	Max. error	1.10	1.02
	Min. error	0.27	0.06
Mixed (85 states)	ME	-1.06	-0.66
	MAE	1.06	0.66
	SD	0.80	0.51
	Max. error	1.33	0.80
	Min. error	0.28	0.18
Rydberg (91 states)	ME	-0.76	-0.47
	MAE	0.76	0.47
	SD	0.85	0.54
	Max. error	1.20	0.80
	Min. error	0.51	0.19
Total (240 states)	ME	-0.82	-0.53
	MAE	0.82	0.53
	SD	0.78	0.51
	Max. error	1.33	1.02
	Min. error	0.27	0.06

TABLE V. Computed vertical excitation energies (E_v in eV) compared to the corresponding positions of the band maxima in the available experimental UV photoabsorption spectra of the Halons-9 set. The computed oscillator strengths for the transitions are also given (f).

Molecule	State	EOM-CCSD		DFT/MRCI		TD-CAM-B3LYP		Exp.
		E_v	f	E_v	f	E_v	f
