Optical spin-dependent beam separation in cyclic group symmetric metasurface

Yeon Ui Lee, Igor Ozerov, Frédéric Bedu, Ji Su Kim, Frédéric Fages and Jeong Weon Wu*

Abstract: Cross-polarization scattering of a circularly polarized beam from nano-rod introduces a geometric phase to the outgoing beam with opposite circular polarization. By manipulating the spatial array of subwavelength nano-structure constituting metasurface, the geometric phase can be engineered to generate a variety of beam profiles, including vortex beam carrying orbital angular momentum via a process called spin-to-orbital angular momentum conversion. Here we introduce a cyclic group symmetric metasurface composed of tapered arc nano-rods and explore how azimuthal angular distribution of total phase determines the feature of spin-dependent beam separation. When scattered from a circular array of tapered arc nano-rods possessing varying width with a fixed length, a dynamical phase having non-constant azimuthal gradient is introduced to an incoming Gaussian beam. This leads to a spin-dependent beam separation in the outgoing vortex beam profile, which is attributed to an azimuthal angle dependent destructive interference between scatterings from two plasmonic excitations along the width and the length of tapered arc nano-rod. Relation of cyclic group symmetry property of metasurface and the generated vortex beam profile is examined in detail by experimental measurement and analysis in terms of partial-wave expansion and non-constant azimuthal gradient of total phase. Capability of spatial beam profiling by spin-dependent beam separation in vortex beam generation has an important implication for spatial demultiplexing in optical communication utilizing optical angular momentum mode division multiplexing as well as for optical vortex tweezers and optical signal processing employing vortex beams.

Keywords: cyclic group symmetric metasurface; metamaterial; optical spin; vortex beam.

Novelty and impact statement

Vortex beam generation by geometric phase is known. However, a systematic study of relating symmetry property of cyclic group $C_{nh}$ and vortex beam profile is never reported. This work shows that non-constant azimuthal gradient of total phase is the key in controlling azimuthal interference pattern of vortex beam with asymmetric helical wavefront. Noting the importance of vortex beam communications, this work opens a novel way to manipulate interplay between spin- and orbital angular momentum for vortex beam profiling.

1 Introduction

Since the pioneering work of Hasman group on Pancharatnam-Berry (PB) phase to manipulate wavefront of optical beam, [1–5] application of geometric phase has been expanded to metasurface to open a research field of flat optics. [6–10] PB phase is a geometric phase, associated not with optical path but with polarization, which can be utilized for beam deflection or vortex beam generation, when a cross-polarization scattering of circular polarized light (CPL) takes place in an array of sub-wavelength nano-rods. [1–3]

Regarding a helical wavefront formation, a circular array of sub-wavelength scatterers introduces a geometric phase linearly increasing along azimuthal direction, allowing spin-to-orbital angular momentum conversion to generate a vortex beam possessing topological charge. Examples include metal nano-rods patterned from computer-generated holograms, [3] liquid crystal $q$-plate, [11]
2 PB phase from linear and circular arrays of nano-rods with uniform thickness

We compare linear and circular arrays of eight sub-wavelength nano-rods in providing PB phase through cross-polarization scattering of CPL Gaussian beam. Eight nano-rods rotated in the xy-plane by an angle \( \varphi \) with respect to the neighboring one are schematically shown in Figure 1 (a) and (b) and inset. In Figure 1 (c) PB phase is illustrated in Poincaré sphere, where colored circles correspond to each nano-rod rotated by an angle \( \varphi \) providing a geometric PB phase of \( 2\varphi \) with phase factor of \( e^{i2\varphi} \) for LCP (C) incident beam [2, 3].

In the linear array, a constant PB phase gradient leads to a beam deflection in cross-polarized scattering. The array of nano-rods with uniform thickness provide a constant linear gradient with opposite signs for the left and the right polarized light, deflecting the corresponding beams in opposite directions as Figure 1 (d) and (e).

In the circular array, on the other hand, a constant PB phase gradient takes place in azimuthal direction \( \varphi \) providing a spiral phase shift. [23] Importantly, as shown in Figure 1 (c), the polarization states in Poincaré sphere go through a circular trajectory twice providing the solid angle of \( \pm8\pi \), which corresponds to geometric phase of \( \pm4\pi \), generating vortex beam of topological charge \( l = \pm2 \), as shown in Figure 1 (f) and (g).
 Optical wave scattered from the circular array acquires the geometric phase factor coming from a circular closed path $C$ in Poincaré sphere Stokes parameter space, $\oint d\gamma(C) = \pm 4\pi$ with a constant azimuthal gradient $\nabla_{\phi}\Phi_{PB} = \pm 2$. The intensity profiles of $I_{\pm}(r, \phi) = |E_{\pm}|^2$ and $I_{\pm}(r, \phi) = |E_{\pm}|^2$ are degenerate even though helical handedness is opposite for $l = \pm 2$, where $(\pm \pm) = \{\text{out, in}\}$ stands for left-circular polarization (LCP, $\sigma^+$) scattering/right-circular polarization (RCP, $\sigma^-$) incidence and $(\pm \pm)$ vice-versa. In fact, $E_{\pm}(r, \phi) = J_2(k_0 r) \exp(-k_0^2 r^2 + i2\phi)$ and $E_{\pm}(r, \phi) = J_2(k_0 r) \exp(-k_0^2 r^2 - i2\phi)$ with $n$th order Bessel function $J_n(k_0 r)$.

Owing to the rotational invariance of circular array of nano-rods belonging to the cyclic group $C_{coh}$, the azimuthal gradient $\nabla_{\phi}\Phi_{PB}$ is constant, and PB phase is accumulated in sequence by an equal amount originating from two neighboring nano-rods during one full cycle, leading to a $\phi$-independent scattered electric field $J_{\pm n}(r) \exp(-k_0^2 r^2)$.

3 Total phase from circular arrays of nano-rods with non-uniform thickness

Cross-polarization scattering amplitude is determined by optical response of plasmonic resonance of a nano-rod, which depends on oscillator strength and resonance frequency of the nano-rod. Let’s consider a nano-rod of length $D$ and width $d$. See the inset of Figure 1 (a). Upon incidence of an optical beam, there occur plasmonic excitations along two principal axes, i.e., along both long- and short-axis.

When the long-axis is rotated by an angle of $\phi$ with respect to $x$-axis, the short-axis makes an angle of $\theta = \phi + \frac{\pi}{2}$. This leads to phase factors of $e^{i2\phi}$ and $e^{i2\theta} = e^{i2\phi}$ for cross-polarization scatterings from the long- and short-axis excitations, respectively. Note that phases of $2\phi$ are the same, while the scattering amplitudes are opposite in sign. Refer to (5) in Ref. [23]. In other words, there occurs a destructive interference between scatterings from the long- and short-axis excitations, introducing the same amount of geometric phase of $2\phi$.

Now we introduce a circular array of nano-rods with varying width $d$ from # 1 to # 16 having a fixed length $D$, which belongs to the cyclic group $C_{16h}$, as displayed in Figure 2 (a). Scattering amplitude from the long-axis is the same for nano-rods from # 1 to # 16. As the width $d$ increases from # 1 to # 16, however, scattering amplitude from the short-axis excitation increases owing to larger oscillator strength and the plasmonic resonance closer to the optical wave frequency. The amount of a destructive interference increases between long- and short-axis scatterings, leading to asymmetric total cross-polarization scattering amplitude as the width $d$ increases from # 1 to # 16 along azimuthal angle $\phi$ direction.
Polarization states of cross-polarization scattering are plotted on Poincaré sphere in Figure 2 (b). Solid angle subtended by two meridians of cross-polarization scatterings from two neighboring nano-rods with different widths \(d\) is not a constant but depends on azimuthal angular location \(\phi\) of nano-rod, resulting in a spiral trajectory of polarization states from near the north-pole down to near the equator. This leads to \(\Phi_{tot}\) possessing a non-constant azimuthal gradient. That is, \(\nabla_{\phi}\Phi_{tot}(\phi)\) depends on the azimuthal angle \(\phi\), and we can decompose the total phase \(\Phi_{tot}(\phi)\) as a sum of constant and non-constant azimuthal gradient terms,

\[
\Phi_{tot}(\phi) = \Phi_{pb}(\phi) + \Phi_{D}(\phi).
\]

with \(\Phi_{pb}(\phi)\) possessing a constant azimuthal gradient \(\nabla_{\phi}\Phi_{pb}(\phi) = \pm 2\). Here we note that the presence of a non-constant azimuthal gradient term \(\Phi_{D}(\phi)\) originates from \(\phi\)-dependent width of TA plasmonic nanostructures, as discussed above.

Azimuthal angular feature of vortex beam profiles \(I_{\rightarrow}(r, \phi)\) and \(I_{\leftarrow}(r, \phi)\) is determined by \(\phi\)-dependence of \(\Phi_{tot}(\phi)\). Circular array in Figure 2 (a) belongs to the cyclic group \(C_{nh}\). From the viewpoint of symmetry property, the lowering of rotational symmetry from \(C_{cyc}\) to \(C_{th}\) leads to non-vanishing of \(\Phi_{D}\). As a result, asymmetric helical wavefront is formed and spin-dependent separation takes place with asymmetric vortex beam profile. Bight and dark spots are separated along \(x\)-direction for both LCP \(\sigma^{+}\) and RCP \(\sigma^{-}\) Gaussian incidence beams as displayed in Figure 2 (c) and (d). The reason why the separation takes place along \(x\)-direction will be discussed in terms of the magnitude of azimuthal gradient \(\nabla_{\phi}\Phi_{tot}(\phi)\) in Section 5.

### 4 Total phase from circular array of nano-rods with rotational symmetry of cyclic group \(C_{nh}\)

Now we introduce metasurface composed of circular array of TAs, which belong to a well-defined cyclic group \(C_{nh}\) to study the relationship between cyclic group symmetry property of metasurface and the generated vortex beam profile. Schematics of six different tapered arc cyclic group symmetric metasurfaces (TA-CGSM) are shown in Figure 3 (a).

#### 4.1 Symmetry properties of cyclic group \(C_{nh}\)

We note that there exits an important difference between \(C_{nh}\) of even and odd numbers of group order \(n\) with respect to reflection \(\sigma_{h}\), inversion \(i\) and \(C_{2}\) (\(\pi\)-rotation around \(z\)-axis) operation elements. While \(\sigma_{h}\) is an element of both \(C_{nh}\) (even \(n\)) and \(C_{nh}\) (odd \(n\)), \(i\) and \(C_{2}\) are elements of \(C_{nh}\) (even \(n\)), not of \(C_{nh}\) (odd \(n\)). Furthermore, for \(C_{nh}\) (even \(n\)), the product of \(\sigma_{h}\) and \(i\) elements is equal to \(C_{2}\) element, i. e., \(\sigma_{h} \cdot i = i \cdot \sigma_{h} = C_{2}\).

In terms of these symmetry properties of cyclic group \(C_{nh}\), two important features of cross-polarization scattering beam profiles will be discussed. First, \(\sigma_{h}\) element of \(C_{nh}\) is responsible for rotational symmetry property of the intensity profiles of \(I_{\rightarrow}(r, \phi)\) and \(I_{\leftarrow}(r, \phi)\) in \(C_{nh}\) (both even and odd \(n\)) TA-CGSMs. Second, the intensity difference \(\Delta I = I_{\rightarrow} - I_{\leftarrow}\) depends on the relation between \(E_{\rightarrow}(\phi)\) and \(E_{\leftarrow}(\phi)\) as well as \(\Phi_{tot}(\phi)\) and \(\Phi_{tot}(\phi)\) in \(C_{nh}\) (even \(n\)) TA-CGSMs, which is dictated by \(\sigma_{h}\), \(i\), and \(C_{2}\) elements of \(C_{nh}\) (even \(n\)).
4.2 Sample fabrication and experimental result of spin-dependent beam profile measurements

In Figure 3 (a) are shown schematics of TA-CSGM, where each TA-CSGM is composed of multiple TA nano-rods with varying width \(d\) from 45 nm to 150 nm placed in eight azimuthal segments of concentric rings repeated with 600 nm radial spacing. Figure 3 (b) shows optical microscope images of the fabricated TA-CSGMs belonging to cyclic groups \(C_{\infty h}, C_1 h, C_2 h, C_3 h, C_4 h, C_5 h,\) and \(C_6 h\) for \(I_{-+}\) and \(I_{+-}\), respectively, measured with \(\lambda = 1310\) nm incidence Gaussian beam. (g) Plot of the intensity difference \(\Delta I = I_{-+} - I_{+-}\).
5 Discussion

5.1 Symmetry property of vortex beam profiles under $\sigma_h$ and $C_2$

Far-field electric fields of asymmetric vortex beams shown in Figure 3 (e) and (f) can be described as below.

\[ E(r, \phi)_{+} = A(r, \phi)\exp[\mathrm{i} \Phi_{\phi}^+(\phi)] \]
\[ E(r, \phi)_{-} = B(r, \phi)\exp[\mathrm{i} \Phi_{\phi}^-(\phi)] \]

where the azimuthal gradient of $\Phi_{\phi}^+(\phi)$, $\nabla_{\phi} \Phi_{\phi}^+(\phi)$, is $\phi$-dependent.

Regarding $\Phi_{\phi}^+(\phi)$ and $\Phi_{\phi}^-(\phi)$, we note that the spiral trajectory for $+\phi$ is the mirror image of that for $-\phi$ with the equator plane of Poincaré sphere as a mirror plane, i.e., the senses of rotation are opposite to each other. This leads to the relation of total phases $\Phi_{\phi}^+(\phi) = -\Phi_{\phi}^-(\phi)$, the same in magnitude but opposite in sign. See Figure 4 (d), (e), (D), and (E). Furthermore, since $C_{nh}$ TA-CGMS is invariant under $\sigma_h$ operation, scattering amplitude of $+\phi$ from $C_{nh}$ TA-CGMS is the same as that of $-\phi$ from $n$-rotated TA-CGMS, i.e., $E(r, \phi)_{+} = E(r, \phi + n)_{+}$. Accordingly, we obtain the relation of $I_{+} (\phi) = I_{+} (\phi + n)$ between scattering intensities of $-\phi$ and $+\phi$. See Figure 3 (e) and (f) and Figure 4 (a), (b), (A), and (B). This is true for $C_{nh}$ (both even and odd $n$) TA-CGMS.

On the other hand, $C_{nh}$ (even $n$) TA-CGMSs is invariant under a simultaneous operations of $\sigma_h$ and $i$, which is equivalent to the invariance of $C_{nh}$ (even $n$) TA-CGMS under $C_2$ operation. That is, scattering amplitude from $C_{nh}$ (even $n$) TA-CGSM is the same as that from $n$-rotated $C_{nh}$ (even $n$) TA-CGSM. In other words, $I_{+} (\phi + n) = I_{+} (\phi)$ and $I_{-} (\phi + n) = I_{-} (\phi)$. Combining with the above relation $I_{+} (\phi) = I_{+} (\phi + n)$, we obtain $I_{+} (\phi) = I_{+} (\phi)$, which leads to that $\Delta I = I_{+} - I_{-}$ is null for $C_{nh}$ (even $n$) TA-CGSMs, but not for $C_{nh}$ (odd $n$) TA-CGSMs. See the plot of $\Delta I = I_{+} - I_{-}$ in Figure 3, similar to what is reported in Ref [24].

5.2 Partial-wave expansion and azimuthal interference pattern

5.2.1 Partial-wave expansion

TA-CGSM renders azimuthal gradient $\nabla_{\phi} \Phi_{\phi}^+(\phi)$ of cross-polarization scattering beam to be $\phi$-dependent, leading to $\phi$-dependent helical wavefront, equivalently, to $\phi$-dependent scattering amplitude in far-field as shown in experimental measurements of Figure 3 (e) and (f). This indicates that the scattering amplitude is composed of vortex beams of topological charge not only $l = 2$ but also $l \neq 2$.

Bessel-Gaussian (BG) beam satisfies a paraxial equation of propagation and it describes an azimuthal symmetric intensity distribution carrying orbital angular momentum. We note two properties of BG beams relevant to the spatial beam profiles observed in our experiment for a series of TA-CGSMs. The first property is that BG beams can be built up by a superposition of decentered Gaussian beams, whose centers are positioned on a circle and the beam direction of which points to the apex of a cone. This is related to $C_{coh}$ TA-CGSM, where the azimuthal symmetric annular beam intensity results from a superposition of decentered Gaussian beams scattered from each plasmonic segment of $C_{coh}$ TA-CGSM. The second property is that an asymmetric Bessel-Gaussian beam can be represented as a linear combination of symmetric Bessel-Gaussian beams. This is related to $C_{ih}$, $C_{2h}$, $C_{3h}$, $C_{4h}$, $C_{5h}$, and $C_{6h}$ TA-CGSMs, where the spatial beam profile has an annular shape possessing azimuthal angle dependent intensity distribution.

Since $C_{ih}$, $C_{2h}$, $C_{3h}$, $C_{4h}$, $C_{5h}$, and $C_{6h}$ TA-CGSMs are of a ring structure with cyclic group symmetry lowered from that of $C_{coh}$ TA-CGSM, we adopt BG beams as basis in a partial-wave expansion to examine how the symmetry lowering of azimuthal distribution of nano-rods modifies BG beam profile of the scattering light from azimuthal symmetric $C_{coh}$ TA-CGSM. Vortex beam of topological charge $l$ is described by the $l$th order Bessel-Gaussian beam $B_{l}(r)\exp(\mathrm{i} \phi l)$, [27]
where $\text{nth order Bessel function } J_\text{n}(x)$ satisfies a symmetry relation $J_{-\text{n}}(x) = (-1)^n J_\text{n}(x)$. Now we express $\phi$-dependent scattering amplitude as a linear combination of Bessel-Gaussian beams with partial-wave expansion coefficient $\tilde{a}_l$: [25, 28],

$$E(r, \phi) = A(r, \phi)e^{i\Phi_{\text{tot}}(\phi)} = \sum_l \tilde{a}_l B_{Gl}(r)e^{il\phi} \quad (3)$$

$$\tilde{a}_l \equiv a_l e^{il\phi} \quad (4)$$

where $\tilde{a}_l$ is the $l$th order expansion coefficient of Fourier expansion, $A(r, \phi) = |E(r, \phi)|$ is the amplitude, and $\Phi_{\text{tot}} = \Phi_\text{Ph} + \Phi_\text{D} = \tan^{-1} [\text{Im}(E)/\text{Re}(E)]$ is the total phase.

When the second term $\Phi_\text{d}(\phi)$ of (1) is absent, the azimuthal gradient $\nabla_\phi \Phi_{\text{tot}}$ reduces to $+2$, generating a vortex beam of topological charge $+2$. That is, $\tilde{a}_2 = 1$ and $\tilde{a}_l = 0$ for $l \neq 2$ in (3). The presence of $\Phi_\text{D}(\phi)$ of (1) is responsible for additional generation of vortex beams of topological charge $l \neq 2$, and magnitude $a_l$ and phase $\psi_l$ of $\tilde{a}_l$ (l $\neq 2$) in (4) describes how additional vortex beams contribute to determining $\phi$-dependence of scattering amplitude.

Vortex beam profile, i.e., far-field intensity, $I_{\text{..}}(r, \phi) = |E(r, \phi)|^2$, is nothing but the interference pattern between vortex beam of $l = 2$ and additional vortex beams of $l \neq 2$, originating from non-constant azimuthal gradient $\nabla_\phi \Phi_{\text{tot}}$. While magnitude $a_l$ is a measure of contribution of
vortex beam of \( l \neq 2 \), phase \( \psi_l \) plays an important role in determining azimuthal distribution of intensity \( I_{-\phi}(r, \phi) \), that is, the azimuthal location of bright and dark spots observed in vortex beams. An expression similar to (3) holds for \( E(r, \phi)_{-\phi} \) with \( \Phi_{tot}^{-\phi}(\phi) = -\Phi_{tot}^{+\phi}(\phi) \) in (2) as discussed in Section 5.1.

The partial-wave expansion analysis was adopted to relate group order \( n \) of cyclic symmetry in the interference pattern of the partial waves and spin-dependent beam splitting. By employing (3) and (4), i.e., \( I(r, \phi)_{-\phi} = |E(r, \phi)_{-\phi}|^2 \), the partial-wave expansion coefficient \( a_l \equiv a_l e^{i\phi_l} \) is obtained by a least-squared-fit of the experimentally measured intensity profiles \( I(r, \phi)_{-\phi} \) as a function of azimuthal angle in Figure 3 (e) & (f), and the fitted intensity and phase of scattered fields are plotted in Figure 4 (a) & (b) and (d) & (e), respectively. The fit values of magnitude \( a_l \) and phase \( \psi_l \) of \( a_l \) in (4) are listed in Figure 5 (g).

### 5.2.2 Azimuthal interference pattern and correlation between group order \( n \) of \( C_{nh} \) and topological charge \( l \)

Now we study the interference behavior between \( l = +2 \) (or \( -2 \)) and partial-wave vortex beams having difference topological charge \( l \neq \pm 2 \) for \((-\phi \mid \pm \phi \rangle\) scattering originating from \( \phi \)-dependent CGSMs.

In order to identify the correlation between additionally generated vortex beam of topological charge \( l \) and group order \( n \) of \( C_{nh} \), we consider \(-\phi \mid \phi \rangle\) scattering where vortex beam of \( l = 2 \) and additional vortex beam of \( l \neq 2 \) interfere each other. From (3) we have

\[
E(r, \phi)_{-\phi} = A(r, \phi) e^{i\Phi_{tot}(\phi)} = B_G(r) e^{i\phi_l} + a_l e^{i\phi_l} B_l(r) e^{i\phi_l} = e^{i\phi_l} \left[ B_G(r) + a_l B_l(r) e^{i(1/2\phi_l)} \right], \quad (l \neq 2)
\]

In (5) the amplitude \( A(r, \phi) \) is expressed as below.

\[
A(r, \phi) = \left[ 2a_l B_G(r) B_l(r) \cos (l + 2\phi_l) + h \Phi_l \right] + B_l(r)^2 + a_l^2 B_l(r)^2 \right]^{1/2}
\]

Azimuthal angle dependence is described by the first term of (6), which is the interference term. As azimuthal angle \( \phi \) increases from 0 to \( 2\pi \), a constructive interference takes place at azimuthal angle \( \phi_m = m \cdot \phi_0 \) (\( m = \text{integer} \)) with \( \phi_0 \) satisfying the relation \( (l + 2)\phi_0 = 2\pi \). That is, there are \( l \pm 2 \) numbers of bright spots at the intensity \( I_{-\phi}(r, \phi) \) of vortex beam with asymmetric helical wavefront. On the other hand, the interference should possess \( n \)-fold rotation symmetry dictated by group order \( n \) of \( C_{nh} \). Therefore we have the relation between \( l \) and \( n \) as

\[
l = 2 - n
\]

By looking up the table listed in Figure 5 (g) we find that the relation of (7) holds for all \( C_{nh} \) TA-CGSMs. Note that the non-vanishing vortex beams of \( l = -1 \) for \( C_{1h} \) and \( l = 2 \) for \( C_{2h} \) have the helicity opposite to that of generated vortex beams of \( l = +1 \) for \( C_{1h} \) and \( l = +2 \) for \( C_{2h} \), and the interference term of two vortex beams of opposite helicities \(+l \) and \(-l \) is not \( \phi \)-dependent as can be seen easily in (5) when \( a_{-l} \) is added.

Partial wave expansions with fit values listed in Figure 5 (g) are explicitly expressed as below for \( C_{1h} \) TA-CGSM,

\[
E(r, \phi)_{-\phi} = B_G(r) e^{i\phi_l} + 0.24B_{1G}(r) e^{i\phi_l} \exp \left( \pm \frac{i3\pi}{2} \right)
\]

and for \( C_{2h} \) TA-CGSM,

\[
E(r, \phi)_{-\phi} = B_G(r) e^{i\phi_l} + B_{1G}(r) e^{i\phi_l} \exp (+inr)
\]

From Eqs. (9)–(10) the intensity and phase of the sum of \( l = \pm 2 \) vortex and partial-wave vortex beams are plotted for \((-\phi \mid \phi \rangle\) scattering in \( C_{1h} \) TA-CGSM and \( C_{2h} \) TA-CGSM as displayed in Figure 4 (f) & (g) (Figure 4 (h) & (i)) and Figure 4 (l) & (m) (Figure 4 (l) & (m)), respectively. We find that \( \Delta I = I_{-\phi} - I_{+\phi} = 0 \) for \( C_{1h} \) and \( \Delta I \neq 0 \) for \( C_{2h} \) TA-CGSMs.

We also adopted finite difference time domain (Lumerical FDTD) method to calculate the far-field intensity \( \langle I_{-\phi} \rangle \) and phase \( \Phi_{-\phi}, \Phi_{+\phi} \) distributions of scattered field from \( C_{nh} \) metasurfaces. See Figure 4 (A-E) for FDTD calculation, which is in a perfect agreement with experimental results.
5.3 Non-constant azimuthal gradient of total phase

Now we identify how non-constant azimuthal gradient of dynamical phase is related to the vortex beam profile, in particular, the distribution of bright and dark spots. As discussed in Section 3, a destructive interference takes place between cross-polarization scatterings from the long- and short-axis excitations. Differently from the long-axis excitation scattering, the short-axis excitation scattering is \( \phi \)-dependent for \( C_{nh} \) TA-CGSM, leading to \( \phi \)-dependent interference, which is associated with \( \phi \)-dependent \( \nabla \phi D \) in (1) as illustrated in Figure (2) (b).

From the view point of wavefront manipulation by a local phase control through metasurface, the presence of \( \phi \)-dependent \( \nabla \phi D \) at \( C_{nh} \) TA-CGSM alters the wavefront along the azimuthal direction. To elucidate how a phase gradient across a propagating beam cross-section alters wavefront, let’s consider a simple circular convex lens converging an incident beam toward the center, where dynamical phase \( \Phi_d \) is responsible for refraction.

Along a straight line drawn from one point at the circumference of circular convex lens passing through the center to the other opposite point, linear gradient of dynamical phase, \( \nabla \Phi_d \), changes sign from positive to negative when crossing the center, where the magnitude of \( \nabla \Phi_d \) being the minimum as zero. That is, the alteration of wavefront is minimum at the point having the minimum \( |\nabla \Phi_d| \) across beam cross-section, leading to converging of the incident beam toward the center.

In a similar way, azimuthal gradient of total phase is modulated around the value \( \nabla \phi \Phi_D \)\(|\Phi_D| = +2 \) (\(-2\)) owing to the presence of \( \phi \)-dependent \( \nabla \phi D \), subsequently resulting in an azimuthal alteration of wavefront. In \( C_{nh} \) TA-CGSM, for example, the minimum \(|\nabla \phi \Phi_{D,0}^{\pm}\)\((\nabla \phi \Phi_{D,0}^{\pm})\) takes place at near \( \phi = \pi \) \((\phi = 0 \pm 2\pi)\) at \( \lambda = 1300 \text{ nm} \), leading to converging of the incident beam along the azimuthal direction toward the angle near \( \phi = \pi \) \((\phi = 0 \pm 2\pi)\) of the single bright spot. Dependence of scattering intensity and phase gradient on azimuthal angle \( \phi \) is compared in Figure 5. See Figure 5 (e) and Figure 5 (f) for \((+-)\) and \((-+)\) scatterings, respectively. The number of bright spots is equal to the number of the local minimum \(|\nabla \phi \Phi_{D,0}^{\pm}|\) in both \((+-)\) and \((-+)\) scatterings.

We note that the symmetry dictated by \( \sigma_h \) operation leads to \( l_+ \) \((\phi) = l_- (\phi + \pi)\) as discussed in Section 5.1. In fact, the coincidence of angular locations of a bright spot and a local minimum of \(|\nabla \phi \Phi_{D,0}^{\pm}|\) is evident as seen in the plot of Figure 5 (a) and (c). Refer to Figure 2 of Supplementary Information for \( C_{nh} \) TA-CGSMs \((n \neq 1)\).

In fact, the azimuthal distribution of bright and dark spots and radial node lines in cross-scattering intensity results from interplay of \( \phi \)-independent \( \nabla \phi \Phi_{D,0}^{\pm}\) and \( \phi \)-dependent \( \nabla \phi D \). In other words, the original helical wavefronts with the azimuthal geometric phase gradient \( \pm 2 \) are altered by an introduction of non-constant azimuthal gradient \( \nabla \phi D \), to focus wavefront along azimuthal direction to build a bright spot, similar to focusing wavefront along radial direction by optical antenna metasurface in flat optics. [6–10]
5.4 Wavelength dependence of spin-dependent beam separation

As noted in Section 3, there occurs a destructive interference between scatterings from the long- and short-axis excitations, which is responsible for vortex beam profiles when cross-polarization scattered from for C_{nh} TA-CGSMs. In a given C_{nh} TA-CGSM, TA has a varying width with the same fixed length, and scattering amplitude from plasmonic excitation along short-axis of the varying width depends on plasmonic resonance. This leads to that the spin-dependent beam separation in vortex beam generation depends on wavelength of incident Gaussian beam.

We performed experimental measurement of spin-dependent beam separation of C_{1h} TA-CGSM by employing lasers with different wavelengths. Single-mode fiber pigtailed laser diodes with wavelengths λ = 1310 nm, λ = 730 nm, and λ = 660 nm are adopted as normal-incidence Gaussian beam sources. Azimuthal interference pattern goes through clock-wise rotation as wavelength gets shorter as shown in beam profile measurement and FDTD simulation at the top panel of Figure 6.

It is known that geometric phase is non-dispersive. However, scattering amplitude from short-axis excitation depends on the relative spectral location of incident beam wavelength with respect to plasmonics resonance. Subsequently, the location of polarization state at Poincaré sphere depends on the incident beam wavelength. As a result, non-constant azimuthal gradient ∇φ_{P} is dispersive.

In order to confirm that dispersive ∇φ_{P} is responsible for wavelength-dependent azimuthal interference pattern from C_{1h} TA-CGSM, we examined C_{1}' metasurface composed of two semicircles with different thicknesses as shown at bottom-left panel of Figure 6, which possesses σ_{yz} symmetry, i.e., reflection symmetry with respect to yz-plane. FDTD simulation of cross-polarization scattering shows that spin-dependent vortex beam separation.
takes place always along x-direction for all three different wavelengths as shown at the bottom panel of Figure 6. Scattering from one semi-circle results in one full circle of polarization states in Poincaré sphere, and thereby introduces $2\pi$ of PB phase for each semi-circle as discussed in Section 2. However, the difference in thickness of two semi-circles results in $\nabla_\phi \Phi_{tot} \neq \pm 2$ at $\phi = 0 \& \pi$, regardless of incident beam wavelength. As a result, a vortex beam with asymmetric wavefront is generated, which is composed of vortex beams of $l = \pm 2$ and $l = \pm 1$ as shown in Tables 1, 2, and 3.

A careful examination of the bottom panel of Figure 6 shows that there occurs a beam deflection in vertical direction along with spin-dependent vortex beam separation in horizontal direction. This is an example of beam deflection according to generalized Snell’s law.\cite{29, 30} That is, the existence of $\nabla_\phi \Phi_{tot}$ along y-direction is equivalent to the presence of phase discontinuity along y-direction, giving rise to $\delta \tilde{k}$ in linear momentum $\tilde{k}$ of scattered vortex beam along y-direction, and a vertical deflection of vortex beam takes place, which is wavelength-dependent. In $C'_1$ metasurface, the minimum $|\nabla_\phi \Phi_{tot}|/|\nabla_\phi \Phi_{tot}|$ takes place at $\phi = \pi$ ($\phi = 0 \equiv 2\pi$). Owing to $\sigma_{xx}$ symmetry, the net gradient of $\tilde{\phi}$-dependent $\nabla_\phi \Phi_{tot}$ is located at $\phi = \pi$ or $\phi = 0 \equiv 2\pi$ with direction along $\tilde{\phi}$ corresponding to $-y$ direction for both $(-\rightarrow)$ and $(+\rightarrow)$ scatterings, which leads to $\delta \hat{p}_y$ along $-\hat{y}$.

Consequently, photonic spin Hall effect takes place as a spin-dependent separation of vortex beam in horizontal direction. Berry curvature is the topological magnetic monopole, $\nabla \times \hat{B}(p) = \hat{p}/p^2$, and Lorentz equation of motion in momentum space is $\delta \hat{x} = \sigma \delta \hat{p} \times \hat{B}(p)$. In helical wavefront, mean momentum $\langle \hat{p} \rangle$ is along the vortex beam propagation direction and takes part in Lorentz equation of motion, i.e., $\delta \langle \hat{x} \rangle = \sigma \delta \langle \hat{p} \rangle \times \hat{B}(\langle \hat{p} \rangle)$. Hence, the transverse shift owing to photonic spin Hall effect takes place in $-\hat{x}$ and $+\hat{x}$ directions for incident LCP ($\sigma = +1$) and RCP ($\sigma = -1$) Gaussian beams, respectively, as displayed in the bottom panel of Figure 6.\cite{31, 32} The interpretation of spin-dependent beam separation for $C_{nh}$ in terms of photonic spin Hall effect is not straightforward due the difficulty in identifying the net gradient of $\tilde{\phi}$-dependent $\nabla_\phi \Phi_{tot}$.

Normalized horizontal (X) and vertical (Y) spin-dependent beam separation profiles, $\Delta I(X)$ and $\Delta I(Y)$ along the dashed coordinate axes, are displayed in two right panels, where $\Delta I = I_{+}(r, \phi) - I_{-}(r, \phi)$.

### 6 Conclusion

Tapered arc cyclic group symmetric metasurface is introduced to explore the details of optical spin-dependent beam separation in spin-to-orbital angular momentum conversion. Presence of non-constant azimuthal gradient of total phase is found to be responsible for azimuthal interference pattern in vortex beams with asymmetric helical wavefront. By identifying the role of non-constant azimuthal gradient of total phase in giving rise to spin-dependent beam separation, spatial separation and vortex beam profiling are achieved in a controllable manner.

Azimuthal interference pattern in vortex beams with asymmetric helical wavefront found to be related to symmetry property of cyclic group \( C_{n\theta} \), and group order \( n \) determines topological charge \( l \neq \pm 2 \) of additional vortex beams. Our work enhances a fundamental understating of interplay between spin- and orbital angular momentum of light in metasurface. Also our finding provides a significant advantage in applications such as vortex multiplexing in optical communication and optical tweezers employing vortex beams.
